
The Clinical Diagnosis OF CARCINOMA OF THE BREAST.

BY WILLIAM H. BATTLE, F.R.C.S. ENG.,
CONSULTING SURGEON TO ST. THOMAS'S HOSPITAL, ETC.

(With Illustrative Plates.)

THE importance of the early recognition of a carcinoma which has arisen in any part of the body is fully appreciated by the medical profession, as the possibility of successful treatment depends so greatly on the stage at which operation is permitted. At the present time we know of no other method of interference which affords a chance of cure. It might be considered that in an organ which is situated as the breast it would be quite easy to distinguish a malignant from a simple growth, but this is not so in the early stages, especially when the patient is well nourished. Dr. Hort[1] states that 128 out of 300 patients under the age of 25 suffering from disease of the breast were not diagnosed correctly. He makes a further statement that 582 out of 3532 were sent to London hospitals with a wrong diagnosis.

EARLY STAGES OF CARCINOMA OF THE BREAST.

There is no pain in the early stage, when changes in the breast are but slightly marked, and require an expert to interpret them. To this statement there are few exceptions. The majority of patients present themselves when the nature of the disease is evident and the probability of successful treatment by any method doubtful. A series of photographs which have been taken of cases when they first came under observation proves this very decisively. From year to year it has been the same experience in hospital work—few have come unless there has been a change of marked character in the nipple or in the skin over the breast, or unless a pain has become so insistent that it can no longer be tolerated. In most of these advanced cases there was no loss of flesh, and the general appearance of the patients was unaltered.

A small proportion say that they did consult someone when they first felt a lump in the breast, but that they were reassured as to its nature—as it was small, discovered by accident when washing, and did not cause pain, they were told not to trouble any more about it. They were quite satisfied to follow this advice until they noticed an alteration in the appearance of the breast or pain supervened. The opportunity of giving permanent relief may then have passed for ever. Most of us have made mistakes in the diagnosis of carcinoma of the breast in its early stage. Possibly a first opinion was given after insufficient examination, but whatever the reason of the wrong diagnosis, what a tragedy was staged for a later appearance.

It is hoped that some remarks on the clinical aspects of the disease may lead to an earlier application for relief, and less hesitation in giving sound advice. I am inclined to the opinion that there is still too great a disposition to wait for special "text-book" signs. In this way lives are ultimately lost as surely as a man loses his patient with a perforated gastric ulcer if he waits for "loss of liver dullness."

TECHNIQUE OF EXAMINATION.

Every patient who comes with a complaint of something wrong with the breast must be examined thoroughly. Most mistakes are the result of imperfect examination. After preliminary inquiries regarding the duration of the trouble, the way in which it was discovered, the presence or absence of pain, personal and family history should be taken and attention paid to possible causes such as injury and previous disease of the breast. In order to examine the patient satisfactorily it is best to have the chest coverings removed, so that a full view of the part is possible; usually you are offered a keyhole opening with corsets only partly unfastened.

The room should be warm and a covering provided for the shoulders. The hands of the surgeon must not be cold. Look at the chest from the front with the patient standing and the arms hanging naturally by her sides. This gives you opportunity of comparing the two breasts, judging their outlines and comparative size, and changes in the skin and nipple. If the patient lifts her arms above the head, any adhesion to the pectoral fascia will be shown by a simultaneous raising of the affected gland. A satisfactory palpation can be made with the patient lying back in an easy-chair, or in obscure cases when she is recumbent on a couch. The supra-clavicular spaces are most satisfactorily examined when she is sitting in the chair, the examiner standing behind it. The axillary regions can be searched for glandular changes when she is standing, lying, or sitting if the muscular boundaries of these parts are relaxed.

If we suppose a case in which a solitary lump has been noticed in one breast (the woman is over 30 years of age, says that she is in good health, and looks it), on first examination we see no alteration in either, to the eye they both appear normal. The usual questions have to be answered which arise in the consideration of every abnormal swelling: Is it inflammatory in origin; if not, is it solid or fluid: is it simple or malignant? By far the most common of all malignant growths of the breast is carcinoma (scirrhus—spheroidal-celled, especially the atrophic variety). Bryant estimated that 83 per cent. of breast tumours were carcinoma. Commonly a slowly growing tumour of stony hardness, it gradually replaces the mammary tissue, invades surrounding structures, and affects the lymphatic glands.

The patient should be requested to point exactly to the part of the breast in which she has noticed a swelling, and examination should be gently carried out to ascertain if any of the characteristics of scirrhus are present.

First Stage of Tumour.

This may be called the first stage, and it is most important that some decision should be reached as regards the nature of the swelling. The signs which we look for are the hardness of the tumour, especially in its central part, where there may be some nodulation of surface. It is important to note if the outline of the hard area is irregular and fades gradually into the breast substance or is clearly defined. A thinning of the overlying subcutaneous tissue may be noted. There may be no tenderness, but many patients complain of aching at night-time after the examination. In rare instances small scirrhous growths may be rounded and clearly defined, although very hard. They sometimes appear pedunculated, but soon become fixed to surrounding structures. Their want of elasticity should compel suspicion of them. In these there appears to be a definite limiting membrane which for a time resists the usual infiltration of parts adjacent. In coming to a conclusion as regards the signs mentioned it is advisable to place the patient on a couch whilst examination is made. The first two fingers of the left hand should be placed above and below the swelling, whilst the hand steadies the breast over the chest. The tip of the forefinger of the right hand is then placed over the centre of the swelling and the question of fluctuation decided. No other tumours possess the same stony hardness as carcinoma if we except chondro-sarcoma, osteo-chondro-sarcoma, and sclerosing tuberculous mastitis, all very rare conditions.

If a patient comes with a lump which has these characters, it should be explored without undue delay.

Second Stage of Tumour.

There is nothing to signalise the passing from the first to the second stage of carcinoma of the breast, and it is usually in an advanced period of the second stage that patients present themselves. (Mayo says about

25 per cent. are already inoperable.) It may be difficult to find out when the disease really commenced, for so often the sufferers will not admit there was anything before they "accidentally" discovered it. Sometimes, however, they confess to a longer history on closer questioning, say they were afraid it might be cancer, but there was no pain, and therefore they did not like to make a fuss; they may also add that there had been little change, but because it did not go away they felt it might be best to make certain. One patient admitted that she had concealed her trouble from her husband because their finances were low; another said she did not believe in doctors, and therefore had not shown it.

There is one sign which is found comparatively early and which may be present before the skin gives signs of becoming adherent in front, and that is an elevation of the affected breast when the arms are lifted above the head. It is a proof that the tumour has become attached to the fascia over the muscle, and may be demonstrated when the growth appears to be quite unattached to deeper parts on ordinary examination. A growth which has commenced in the posterior part of the breast is the more likely to give this sign, and it is in obscure cases that it is most valuable. Later, an involvement of the pectoral fascia and muscle ensues; the growth may still be movable across the line of the pectoral fibres, but not when an attempt is made to carry it upwards and outwards. Still later it becomes quite fixed whether the muscle be contracted or not.

This fixation to the parts behind the breast may be unaccountably delayed, as shown by the case of a patient, aged 72, seen in consultation on account of recurring hæmorrhage from a large ulcer of the left breast. The tumour had been slowly growing for more than four years, but as it was painless, and the offensive smell when ulceration supervened could be controlled by applications, she had refused medical aid. There was a large lobulated growth of colour varying from red to purple; three of the most prominent lobules were ulcerated. From one of these there had been considerable bleeding for a month which was increasing in severity, so that she was markedly anæmic. The breast was freely movable, and no enlargement of the axillary glands could be felt. Operation afforded much relief, and recovery was uneventful.

The period at which glandular infection occurs is unknown. Experience has proved the danger of not removing the axillary glands in all cases, although disease of them cannot be demonstrated, no matter how recent the history given. It is not an uncommon experience to be told that they are not enlarged, when more careful examination shows that one or more are, but hidden under the anterior axillary fold, or placed high up in the axilla. It is a good plan to engage the assistance of the patient's friend, or medical attendant if present, and have the arm lifted from the side with the shoulder muscles relaxed. The left hand should be used for the right axilla, whilst the surgeon stands on the patient's left side and vice versa. The flat hand is passed to the apex of the axilla and worked slowly downwards along the posterior margin of the pectorals. The other side should then be examined in a similar way. Generally one or more hard glands can be felt, as they escape upwards from under the finger. This examination must be conducted gently, for the part is somewhat sensitive to pressure. Unusual hardness is of more importance than a slight increase in size, the large gland may not be diseased. Always compare the two sides.

Changes in the supraclavicular glands are not manifest in the early stage of most carcinomata of the breast, but may be demonstrated at a later stage or when the disease commenced in the upper segment. In this region the transverse process of the lowest cervical may be mistaken for a gland, also the posterior belly of the omo-hyoid.

One sees occasionally an extensive development of scirrhous growth in the axillary glands, probably in a stout well-nourished patient, when there is no primary lesion to be found in the breast. It is sometimes in the outer margin in what is called by Deaver the axillary tail, hidden by the mass of diseased glands, or it may have had its origin in an accessory mamma. The disease is never primary in the glands; cases are described where the primary growth, which had been overlooked, was situated in a duct, or had commenced as a small ulceration of the nipple (Lockwood).[2] After the examination of the axilla, it is well to look for nodular developments in the lymphatics, which pass between the breast and axillary glands. The glands which are placed between the pectoral muscles cannot be felt by palpation under ordinary conditions; even when the axilla is opened it may be impossible to feel them. Hence, one of the chief reasons for removal of the pectorals in all operations which aim at eradication of the disease. They are seen lying between the muscles after operation in early cases small, but diseased, and it has been necessary to remove the muscles some weeks after amputation of the breast and clearance of the axilla by others, because of renewed growth invading them from the glands. Early extension to the skin, making it adherent, is demonstrated by lifting the overlying skin between finger and thumb, when it dimples. Later it is adherent over a varying area and cannot be lifted, the growth has infiltrated it. Other changes ensue in scirrhus of the atrophic type, and dimples, grooves, and depressions of varying size and shape form. These are shown in photographs, and are present in the great majority of our hospital patients, when they first apply. A groove may be quite extensive, and it is found that the nipple is not only contracted but concealed in it, or the depression may be in the lower part of the breast and of such a shape as to suggest that the pressure of a corset may have had something to do with the causation of the growth. (Fig. 2.) This particular groove is uncommon.

As these changes develop in the skin and subcutaneous tissue, diminution in size takes place in the breast and nipple, the extent of which will vary with the position of the growth and the rate of contraction. In the atrophic form growth may progress very slowly indeed, one of the characteristic features being the small size of the resultant tumour, considering its duration. There appears to be a constant struggle between the fibrous stroma and the cellular elements; the former, prevailing, often prevents the development of a large tumour, causing a destruction of cellular elements, while it destroys the breast, which is replaced by an irregular, sullen, contracting and deforming deposit. The extremely retarded action of these growths is shown in Fig. 3, where the scirrhus had a history of more than 11 years, during which it caused no inconvenience and when removed was not larger than half a bitter almond. It was spheroidal-celled, but the axillary glands were still unaffected.

The nipple in the second stage will be drawn in from its original position and towards the growth, whilst an early sign is that of a cord passing between the two points, probably the result of permeation of a duct. The shape of the areola is changed, being narrowed on the side towards which the nipple is drawn. In the hypertrophic form (Fig. 1) of spheroidal-celled carcinoma where the tumour is more cellular and prominent, the skin is soon infiltrated with cells, which gradually change it into a part of the tumour with alteration in colour and tendency to break down. The nipple may also be much enlarged in every direction and hardened.

Various cystic and other changes may take place in carcinomatous growth, and a mucoid or colloid degeneration develop. A cyst may be formed as the result of breaking down of a quickly-growing tumour. There are also several instances known of the formation of spheroidal-celled carcinoma in what appears to be a simple cyst. The following instance is instructive:—

A married woman, aged 52 years, had a two years' history of enlargement of the outer segment of the right breast. This had been painless and consisted of two or three large bulging cysts. There was no abnormal hardness in any part, the skin was freely movable over the tumour, and the breast over deeper parts. The axillary glands appeared normal. After removal some solid material was subjected to microscopical examination, and it was spheroidal-celled growth.

This case strengthens the plea for microscopical examination in all growths which have been removed from the breast. A nodular surface with a history of moderate rate of growth will suggest colloid or mucoid degeneration. One patient, aged 72, with colloid carcinoma of right breast and glands, had undergone removal of the left half of the tongue nine years previously for epithelioma. She could talk well, and there were no signs of recurrence.

True suppuration may occur accompanied by the usual signs of inflammation, and an abscess may require incision. That it is not a simple pyogenic abscess is shown by the history and the excessive hardness of the surrounding parts. Two instances only have come under my notice.

Third Stage of Tumour.

The third stage, that of ulceration, supervenes sooner or later after the skin is involved. The extent of it will vary immensely and there may be more than one ulcer, usually without much fungation. Handley states that on an average ulceration commences two and a half years from the time when the disease was noticed. Three varieties are met with :—

(1) In which several superficial ulcers form on a breast extensively invaded by scirrhous growth. The gland is very hard, the skin thin where it remains, and fixed. This variety (Fig. 5) resembles the appearance produced by extensive tuberculous disease. Compare with Fig. 11.

(2) In Fig. 7 the ulcer has hard raised edges, is clearly defined, the surface is granulated, discharge slight, base fixed ; there was no pain.

(3) A more common type of ulceration is shown in Figs. 6 and 10. It differs from the others inasmuch as the surface is occupied by a mass of cell growth which outstands boldly from the tumour. The tissues around are hard and the skin infiltrated ; the skin is mostly carried forward irregularly at the circumference of the protrusion, portions having so far resisted complete destruction. This type of ulcer is liable to irregular sloughing, and may become very offensive.

Another distressing condition observed was that of a woman with advanced carcinoma of long duration. The surface of the enlarged breast was covered with papillomatous growths, which partly concealed irregular ulcerations, from which a continuous flow of thin acrid fluid of very offensive odour came. No antiseptic could quite overcome this, and a most disagreeable smell pervaded the whole house. She had much pain and was very cachectic.

It is mostly in this stage that proofs of extension of the disease are manifested by increase of the pain, fixation of the breast to the chest wall, enlargement of the supraclavicular glands, and solid œdema of the arm. Œdema of the surrounding skin gradually extends as an intractable thickening and the appearance known as " peau d'orange " is seen (Fig. 4). Sometimes small nodules form in the skin near, and multiply. There may be a general infiltration, slowly extending and stiffening the skin, until the patient is hide-bound, or fixed " en cuirasse." This may occur without signs of cachexia, but is usually associated with it.

DURATION OF LIFE.

The question is not infrequently asked as to the duration of life in carcinoma of the breast, and it is unwise to prophesy. The average is given in some of our text-books as three years, but it is wrong to be too dogmatic in any case. There are few surgeons who cannot point to some instance in which prediction of a rapidly fatal result has been falsified by the subsequent history of the case.

Some years ago an unmarried patient of 84 was seen in consultation who had been suffering for more than 20 years. She showed a large characteristic ulcer measuring about 4 inches across, which replaced the left breast. It was adherent, shallow, with irregular outline, sloughy surface, and somewhat offensive odour. There was also considerable induration in the neighbouring parts from irregular growth. The glands were slightly enlarged and hard. She was of spare figure, but energetic, and had recently been in the city by omnibus without an attendant. There was comparatively little pain throughout the illness, which terminated as a result of bronchitis about a year later.

Handley [3] mentions a case of 40 years' duration.

Discharge from the nipple is not very common in spheroidal-celled carcinoma, but is occasionally seen. The importance of this symptom is difficult to estimate in the absence of any evident change in the breast. It is mostly described as a scanty thin discharge of yellowish colour. A discharge from the nipple may not be caused by a malignant growth, and it may be years before any change in the breast gives a clue to its origin.

A multipara, aged 54, had noticed a discharge from the right nipple for several years. A small swelling had been noticed in the breast for 12 months—which had not increased much in size. This proved to be a chronic proliferative mastitis with cysts.

In a multipara, aged 35, a chronic discharge was associated with the later formation of a swelling above the nipple. This was a simple cystic dilatation of a large duct, without growth in its interior or in its walls.

If pressure over a certain point of the areola increases the flow, and still more if the fluid becomes blood-stained, there is a strong probability that a papilloma is growing in one of the larger ducts, although no tumour is felt. It may be that the growth is a duct or villous cancer. These growths have been regarded by some as less malignant than the other forms of cancer of this region. Perhaps the appearance of the discharge makes the patient seek for advice earlier, and be more ready to accept it. When there is only the occasional escape of a few drops of blood from a nipple, and pressure does not increase the amount, especially at the menopause, it will be advisable to try ordinary remedies and watch the case.

PAGET'S DISEASE.

The nature of Paget's disease, or eczema of the nipple, has been the subject of numerous investigations; some, especially two recently published, are most convincing (Handley,[4] Cheatle[5]). From the careful and thorough examination of specimens removed by operation these investigators have come to definite conclusions: (1) that the disease is carcinoma ; (2) that it is primary in the breast epithelioma.

The appearance of the milder form of eruption is shown in Fig. 9. No change of a carcinomatous nature could be found in most careful examination after removal. In the second of longer standing there was a well advanced carcinomatous ulcer, which had developed to the outer side of the patch, from the underlying breast tissue (Fig. 10). In these instances the skin disease somewhat resembled psoriasis. The more vivid colouring of the definite eczematous type almost suggests malignancy when first seen. Paget wrote that in every case he had been able to watch malignant disease followed within two years. Acting on his advice I have always advised complete removal without delay. Most surgeons can recall cases which have come to their notice in which disastrous results have followed postponement of operation and the trial of local remedies.

It is a very unusual experience to find more than one spheroidal-celled tumour in the same breast. Fig. 8 illustrates its occasional occurrence. The specimen is in the Museum of the Royal College of Surgeons of England. The almost simultaneous appearance of carcinoma on both sides is not unknown, as also the formation of a tumour in the remaining breast after amputation of its fellow.

In acute mammary carcinoma (medullary inflamed cancer, Fig. 14) when the epithelial elements form the greater part of the tumour and the stroma is scanty and vascular we have a great contrast to the other forms. Growth is so rapid that the condition is frequently regarded as acute inflammation of the breast. This is especially so when it begins during the period of pregnancy or lactation. The breast becomes enlarged generally, unduly projecting, and fixed. The skin over it is dullish red in colour, hot,

œdematous, and adherent. "Peau d'orange" is an early change. The temperature rises, and not infrequently the disease is diagnosed as a puerperal mastitis and incisions are made under the impression that there is suppuration present. Dissemination, both local and general, is rapid, whilst operation is usually of little avail to arrest the disease. Mr. P. H. Mitchiner recently met with an example in a girl of 16 who was nursing her first child.

Carcinoma of the male breast is rare, probably not met with on an average in more than 1 in 200 (St. Thomas's Hospital, all cases, 8 in 1642).[6] The local signs are the same as in the female, but it is less difficult to diagnose as it is comparatively superficial. Other growths resembling it occur but are also uncommon.

A man of 44 was sent with a hard nodulated plaque under the right nipple. This was painless and could not be separated from the nipple. There was no glandular enlargement and but a week's history. The breast was removed. Microscopical examination, "fibrosis around the ducts and acini of the gland, like that in the female breast in early fibrosis."

Endothelioma in a multipara, aged 27, was described by Mr. H. B. Robinson.[7] He found two hard nodular masses in the breast with slight dimpling of the skin over one part. Three hard glands were felt in the axilla. The clinical appearances were those of spheroidal-celled growth, but the cut surface did not cup on section. It had a pink colour and well-defined margin.

Malignant disease of the nipple is usually secondary to a scirrhus which is centrally situated in a breast. Primary disease may be epitheliomatous, spheroidal-celled, or columnar-celled carcinoma. The rarity of the primary growth is shown by the statistical reports of St. Thomas's Hospital, 1880–1915, inclusive (primary carcinoma of breast 1642 in number), during which period only three instances were registered. One of them was a spheroidal-celled growth, patient aged 69, another that of a girl of 11 years of age This case was published in THE LANCET.[8] Examination after local resection showed a papilloma to be epitheliomatous, and the axillary glands were taken away at a second operation; they were normal. There is a photograph in my possession of another case, which was brought by Dr. W. Ecklin.

A married woman, aged 52, had noticed that the nipple had been "going in a bit" for about a fortnight. It was one-third smaller than the right, hard, on a rounded hard base which had a raised edge. One hard gland could be felt in the axilla. Mr. S. G. Shattock reported "a duct columnar-celled carcinoma."

The specimen is in the Museum of the Royal College of Surgeons of England.

Attention should be drawn to the advisability of making a general examination of the patient. Although the local disease may appear operable, you must ascertain the absence of secondary growths in the chest, liver, and skeleton. These may have given no symptoms to which the patient draws attention, but the frequency with which secondary carcinoma invades the spine should lead to a careful examination of that part where there is complaint of weakness in walking, pains in the back, or girdle pains. A growth in the femur is often first revealed by fracture of the part, whilst in the humerus the formation of a swelling with but little pain may occur and you may unexpectedly find abnormal mobility at that point. The urine should be examined, as in all operation cases albuminuria may be a serious complication It is possible that those suffering from diabetes may be so improved by the administration of insulin as to permit of operation. But bad results have followed interference when this complication has been met with in the past, even when treatment has temporarily got rid of all traces of sugar from the urine. When the diabetic condition was unsuspected coma has supervened in a day or two, and when apparent recovery under treatment has been obtained, sloughing of the cellular tissue with a return of sugar in the urine ended in death from exhaustion.

DIFFERENTIAL DIAGNOSIS.

The swellings which it may be difficult to distinguish from early carcinoma of the breast are cysts, fibro-adenomata, and chronic inflammation. When the cysts and fibro-adenomata are associated with a local inflammation the diagnosis becomes at times quite impossible. A patch of chronic inflammation may be difficult to define, is often tender, and there may be more than one. The axillary glands are not hard, and if enlarged are not markedly so. There are no changes in the overlying skin, and no adhesion to pectoral fascia. Sometimes there is pain of a neuralgic character. A single cyst in such an area may have an extremely thick wall which, with the surrounding inflammation, conceals the presence of fluid. The tension in such a cyst may be so great that when a puncture is made into it, the fluid scatters for yards around. Peripheral mastitis is frequently seen on the axillary border, affecting both breasts in similar manner. Much pain is caused by it. There is an irregular collection of small swellings which are tender to pressure. A chronic abscess or a galactocele may, for a moment, cause hesitation in giving a decided opinion.

A fibro-adenoma may also occupy a position which, surrounded by inflammation, renders diagnosis impossible. Much will depend on the absence of local

Descriptions of Illustrations on Special Plates.

FIG. 1.—Spheroidal-celled carcinoma, right breast and glands, 16 months' duration. Patient aged 37.

FIG. 2.—Spheroidal-celled carcinoma; skin involved, with "corset groove." Patient aged 50.

FIG. 3.—Spheroidal-celled carcinoma, atrophic. Patient aged 52. Small lump noticed in right breast 11 years, dimpling of skin seven years. States "more dimpling now, but lump smaller."

FIG. 4.—Spheroidal-celled carcinoma, ? 12 months' duration. Retraction of nipple, contraction of skin, peau d'orange. Patient aged 56.

FIG. 5.—Extensive spheroidal-celled carcinoma, with pigmentation around ulcers, ? 12 months' duration. Patient aged 35.

FIG. 6.—Spheroidal-celled carcinoma, atrophic, duration four years. Nipple destroyed by ulceration. Patient aged 70.

FIG. 7.—Spheroidal-celled carcinoma, with ulceration. Patient aged 36. Duration, tumour ? 8 months, ulceration three months.

FIG. 8.—Spheroidal-celled carcinoma, two growths. Patient aged 50. Duration, nine months' outer growth, seven and a half months' inner. Nipple drawn in and towards inner growth; ulceration of outer growth; skin over inner growth infiltrated; glands diseased.

FIG. 9.—Paget's disease, eczema of nipple, six months' duration; nipple partly destroyed. Patient aged 47. Sore nipple, December, 1906, whilst suckling; abscess opened March, 1907, followed by eczema. Clinical laboratory report: chronic inflammation, no carcinoma.

FIG. 10.—Spheroidal-celled carcinoma, with ulceration, and Paget's disease of nipple. Patient aged 65. Duration, eczema seven years, tumour six years, ulceration one year.

FIG. 11.—Tubercle of breast. Patient aged 26. Six years' history of abscess, no history of tubercle. Breast much scarred, nipple retracted, glands enlarged.

FIG. 12.—Round-celled sarcoma of breast, not infiltrating, duration two months. Patient aged 13. Side view, showing clean outline of tumour pushing the skin forward.

FIG. 13.—Melanotic fungating sarcoma of breast, appearing soon after a blow on the breast. Duration 14 months, patient aged 36. Growth almost painless, pedunculated, and easily removed.

FIG. 14.—Acute medullary carcinoma. Duration three months, with pain. Patient aged 38. Large, œdematous, firm breast outstanding from chest wall; nipple and areola less prominent; skin shining with red streaks in it. Axillary glands diseased. General health good.

signs of carcinoma, which should be present judging by the duration of the disease and the size of the swelling.

Sometimes a simple cyst bursts through overstretched skin and a fungating sore develops. The riot of growth is much more evident than in carcinoma, and microscopical examination will clear up the case. If the tumour is a large one of slow growth the probability of carcinoma is remote. Simple growths do not produce the deformity and surrounding changes that are met with in scirrhus.

It is advisable to explore small swellings (especially after the age of 30) about which there is doubt, an incision into or through it, should show even in small malignant ones, a cartilaginous resistance to the knife, a hard edge, a cupping of the surface, on which there is the appearance of the unripe pear. No one can mistake this section for anything else if he has had any experience, but doubtful tumours not giving all these characteristic signs should be submitted to microscopical examination at once. I have for some years sent sections of all breast tumours to a skilled pathologist for independent report—no matter how innocent they might appear. The fundamental sign (Quervain) is "the movability of the tumour in relation to the rest of the breast tissue," the duration of the growth is also important.

A mistake between tuberculous deposit and carcinoma is not usual in the first stage; the local enlargement is insidious, and little may be noticed to excite alarm until suppuration ensues. A primary focus may be found elsewhere. Deaver states that patients who are suffering from tubercle present themselves on an average 12 months after it has begun, and carcinomatous cases apply 30 months after its known commencement. In both there may be glandular enlargement. When there is a more extensive infiltration of the breast with suppuration the destruction may be considerable, but even here the undermining of tissues where sinuses have formed, with thinning of skin and pigmentation, can hardly be mistaken for carcinoma, although there may be a superficial resemblance to one form of carcinomatous ulceration. Compare Fig. 11 and Fig. 5. In tubercle there may be destruction of the nipple when the mischief has commenced near it. As already mentioned, any deposit of tubercle which has undergone calcareous change is very apt to be mistaken for carcinoma. The attention of the profession was first drawn to the occurrence of tubercle in the breast by Sir Astley Cooper,[9] but was practically ignored by writers on this subject until Mr. S. G. Shattock[10] drew attention to it in 1889. During the past 20 years many have recorded investigations on this subject.

In actinomycosis the disease is only recognised by the discovery of granules in discharge from an abscess.

Syphilitic disease of the breast is rare. Primary chancre may resemble a primary malignant growth of the nipple.

In one instance, that of a grandmother, aged 46, who was seen because of a very hard-edged ulcer extending to the left nipple with glandular enlargement, it was discovered at a later period when a secondary rash had developed, that she had been trying to keep a grandchild quiet by putting him to the breast. He had snuffles and other symptoms of congenital syphilis. The nipple had been sore for more than a month. The youngest child was aged 10 years.

This case emphasised the importance of a complete exposure of the chest in spite of remonstrance on the patient's part. The development of gummata in the substance of the breast occurs in three ways:[11] (1) The breast becomes swollen, firm, and irregular masses can be felt and seen; (2) one or two lumps form, and the rest of the gland remains healthy; (3) a large gummatous mass forms. A diffuse syphilitic mastitis leading to fibrosis and enlargement is not unknown.

One example of tertiary disease manifested itself by the formation of a small lump in the mammary tail and many hard lumps in the axilla. The patient was a multipara, aged 57, who had noticed a bruised feeling for 14 days, and on examination had discovered the swelling in the breast margin and numerous lumps under the arm. The segment of breast involved was excised and axilla cleared of many glands. The larger ones on section resembled sarcoma, and were of pinkish yellow appearance. Some of them were quite large. Microscopically, they were gummatous undergoing fibroid changes, the smaller glands being partly replaced by adipose tissue. There was a history of thrombosis of a large vein which had cleared up after a course of iodide of potassium.

Sarcomata of the breast may present some resemblance to carcinomata: (1) in the early stages, (2) when the skin has given way and there is exposure of the growth, and (3) when the tumour has undergone unusual changes. A sarcoma grows rapidly and when first seen has attained a size which in carcinoma would be characterised by adhesion to the skin and extreme hardness with definite involvement of the axillary glands. The sarcoma is more elastic to the touch, well defined, and instead of infiltrating the skin pushes it before it. It is shown in Fig. 12, which is a contour photograph taken by means of the X rays to demonstrate this.[12]

A girl, aged 13, had a swelling the size of a tangerine orange, described as "adeno-sarcoma," noticed for two months, and following a blow. She was again in hospital two years later and a vascular-looking tumour was removed from the left breast. This was reported as "adenoma." Four years later the left breast was removed on account of the formation of two more growths in it. These showed a pink firm section but microscopic characters of adenoma. The glands were not enlarged.

Another illustration, Fig. 13, shows the manner in which a sarcoma fungates when the overlying skin has given way, and no longer exerts pressure on the soft rapidly-growing mass. It was a round-celled growth which followed a blow received 14 months before.[13] The breast was small and the woman, aged 36, was anæmic and very low as the result of repeated hæmorrhages.

Some sarcomata develop cartilaginous change, and so resemble hypertrophic carcinoma in their unusual hardness, but they are usually of more rapid growth, characteristic invasion of surrounding parts is absent, and the hardness is mostly distributed in an irregular manner. In osteo-chondro-sarcomata—in which true bone may be formed—the sensation produced is much like touching a metallic foreign body under the skin. An example of this excessively rare tumour was shown at a meeting of the Pathological Society in 1886.

The tumour was removed by Mr. Mackellar from a woman, 73 years of age. She had noticed a lump in the right breast six years before; it was then the size of a pea and did not grow for two years. It increased to "hazel-nut" size by the end of five years and to that of an orange later on without pain. The nipple was retracted. Skin adherent, red, and tense over the inner part, which was excessively hard. One small hard gland was felt in the axilla.

As a rule, the glands are not affected in sarcoma. Sometimes they are rapidly growing, lobulated, soft, and encapsulated masses.

BUCHANAN HOSPITAL, ST. LEONARDS. — The foundation-stone of the new women's wing of this hospital was laid on Dec. 17th last. The building and equipment is estimated to cost £7000. The new wing is to be named after Dr. Clowes Pritchard. The hospital was originally opened in 1884 and an out-patients' department was added in 1899. Between 300 and 400 in-patients are admitted to the hospital yearly, the number of out-patients exceeding 600.

PNEUMONIA AND ITS COMPLICATIONS.

By WALTER BROADBENT, M.D. Camb., F.R.C.P. Lond.,

PHYSICIAN TO THE ROYAL SUSSEX COUNTY HOSPITAL AND TO THE ROYAL ALEXANDRA HOSPITAL FOR CHILDREN, BRIGHTON.

Pneumonia is a disease which has changed more than any other since I was a student. Then most of the cases were lobar; since the 1890 epidemic of influenza, the broncho-pneumonic and mixed types have been much more common.

A typical lobar case begins suddenly with a rigor, or in children sometimes with convulsions, has a very high temperature for five to eight days, and ends with a crisis, the temperature falling to below normal in less than a day. The face is flushed, respirations are rapid, the pulse should not be quickened quite in proportion to the rise of temperature. For the first day or two there may be none of the physical signs of consolidation, but the affected side of the chest will move less than the other, and the note on percussion will be less resonant. The breath sounds will be weaker than normal, but, though there may not be a suggestion of tubular breathing, vocal resonance is often a little increased. It is in this stage that a right-sided pneumonia may be confused with appendicitis, a patch of diaphragmatic pleurisy which is out of reach of auscultation, giving rise to pain shooting down towards the right iliac fossa, and to rigidity of the abdominal wall; but, in pneumonia, respirations will be rapid, and the right chest will not be moving as well as the left; also, a rectal examination will not reveal any tenderness in the right iliac fossa.

Pneumonia starting in the apex of the lung is, for some unknown reason, more severe than the more usual basal cases. The patient is generally very delirious and there is a greater tendency to hyperpyrexia. In some cases of hyperpyrexia there is a rapid diminution of the physical signs of consolidation, liquid crepitations occurring, and one theory advanced is that there is an unusual absorption of toxic products from the alveoli into the blood, and that this is the cause of the hyperpyrexia. A low temperature in a case with extensive physical signs is of grave import, implying defective resistance. Sometimes in a severe case there is a fall of temperature suggesting a crisis, but the pulse increases in rapidity, and the patient becomes pale and blue, usually dying. The fall of temperature is due to the breakdown of the body's reaction to the bacterial toxins. Often for a day or two before this the pulse is intermittent, which is a bad sign in pneumonia. On examining the blood one should find a leucocytosis, which may be even as high as 50,000, so that blood counts are not very useful as a guide to empyema. A high leucocyte count means a favourable case as a rule, and a low count a bad case. After a crisis the count falls, and, if it then begins to rise again, it does indicate empyema.

Broncho-pneumonia.

Broncho-pneumonia usually starts more gradually than lobar pneumonia, the temperature is not so high, and remits more in the morning. In influenzal epidemics the high temperature of the beginning of an attack may fall for two or three days, and then on the third or fourth day broncho-pneumonia may start and the temperature rise again with increasing illness of the patient. As to physical signs, medium crepitations are heard at the base of the lung, and spread upwards rapidly. Patches of finer crepitations develop, followed by tubular breathing. Dullness is not so absolute as in the lobar form. The area of lung affected may go on increasing for several days. The disease may last ten days or a fortnight, or even longer. In children there is a form of tuberculous broncho-pneumonia which is not distinguishable by physical signs from the pneumococcal, except in that the spread is slower and there is no resolution. It is important in a suspected case to get some sputum for examination; this is always difficult in children.

In influenzal epidemics very severe types may occur. One which might be called the hæmorrhagic begins with high temperature—104° or 105° F. The tongue is quickly dry and brown, and about the third or fourth day there is a profuse hæmoptysis, half a pint of blood or more being coughed up at a time. This is often preceded by severe pleuritic pain. I think that these cases are invariably fatal. Post mortem the lungs resemble those of pneumonic plague, large black blood-clots being scattered through the much congested broncho-pneumonic lung. Another set of cases might be called œdematous; in them, also, the mortality is very great, the temperature is not at all high, but the pulse and respirations are rapid, and the patient is obviously very ill from the start. Crepitations spread all over both lungs from bases to apices, and are very numerous. After only a few days' illness, in most cases, the face becomes a pale bluish-grey and death takes place within 24 hours of this change.

Pleurisy and Empyema.

Pleurisy occurs with all types of pneumonia, and often there is effusion, but aspiration is not advisable before the temperature falls unless there are signs of displacement or embarrassment of the heart, the fluid usually being absorbed. It is, however, a useful precaution, toward the end of the first week, to draw off a syringe-full to see if pus is developing, especially in the case of children, since in them breath sounds can be heard through pus fairly distinctly.

The most ordinary complication is, of course, empyema. In most cases it is quite easy to diagnose; an increasing rise of evening temperature with morning remissions and dullness and silence at the base of the lung with displacement of the heart, pointing definitely to it, but in quite a number of cases matters are not so simple. Difficulties may occur from the situation of an empyema. It is not altogether uncommon between the lobes of the lungs. Sometimes it develops on the side opposite to the pneumonia, which adds to the difficulty of diagnosis. If untreated such an empyema may burst into a bronchus, and after weeks of coughing, sometimes of fœtid sputum, may clear up, or chronic bronchiectasis may result. Physical signs are very varied, depending on which direction the empyema takes towards the chest wall.

In one case that I have seen a man had recovered from a left-sided pneumonia, and had been actually back to work; he had a severe cough and a good deal of expectoration. The temperature was 100° at night, there was dullness in the second and third right spaces in front, and diminished resonance below; bronchial breathing at the apex, distant tubular breathing in the second and third spaces, weak breathing below with coarse crepitations. Over the right back breathing was bronchial and rather weak in the upper half, but there was no dullness. An X ray photograph showed a pear-shaped shadow in the second and third spaces, with some shading of the lower lobe.

Another case was admitted under my care in the 2nd Eastern General Hospital with what appeared to be a large empyema on the left side, there being dullness and silence from the spine of the scapula to the base. Major Buck operated in the usual situation, below and external to the angle of the scapula, but the amount of pus was unexpectedly small and there was no improvement in the general condition, the temperature remaining hectic. A few days later I found that the lower part of the back was slightly resonant, but that just below the level of the spine of the scapula there was an area of absolute dullness about three inches in depth. An aspirator inserted here withdrew much pus, which, however, reaccumulated, and Major Buck removed a portion of the fourth rib between the scapula and the vertebræ and opened a large empyema between the upper and lower lobes of the lung. The operation was one of some difficulty owing to the depth of muscle. In this case the original empyema was evidently inter-lobar, and some of the pus had leaked down over the lower lobe, where it was found at the first operation. The man made a good recovery.

Besides these, I have seen three other cases of inter-lobar empyema, which have been subsequently cured by operation. One of these, however, was not preceded by pneumonia, but by a fall on the chest some weeks before. Mr. Fletcher opened this through the upper axilla and a cure resulted. When much pus collects in an inter-lobar fissure, the lower lobe of the lung becomes compressed and dull, leading to the belief that there is an ordinary empyema. In the earlier stages there may be dullness in the second and third spaces in front, or a band of dullness at the level of the spine of the scapula, and sometimes high up in the axilla, and diminished resonance over the lower lobe. On auscultation over the upper lobe there is weakened bronchial breathing from pressure; over any dull band very weak breath sounds, and below, generally weak and rather bronchial breath sounds with some crepitations. Unfortunately, the physical signs differ in every case. The best place to insert a needle is in the upper axilla with the arm at right angles to the side; this is the seat of election for operation, there being no muscle in the way.

A very rare position for an empyema is between the mediastinum and the lung. An elderly man had a very severe influenzal pneumonia of the left lung, during which he was desperately ill. He had a good deal of pleurisy over the left lower lobe. After a fall the temperature rose again, and the lower lobe of the lung, which had appeared to be clearing, became dull and silent, but no pus was found by exploration. After some days he suddenly coughed up a quantity of pus and continued to do so, the temperature meanwhile remaining hectic, and the lung dull and silent. The patient was then seen by Sir William Osler, who found a strip of resonance about 3 inches broad, just to the left of the vertebral column over the angles of the sixth, seventh, and eighth ribs. He pointed out that, as the patient was spitting up pus, there was probably a pyo-pneumothorax, and he had a needle put into the lower part of the resonant area just external to the angle of the eighth rib. Pus was at once obtained. Later, a piece of rib, just beyond the angle, was resected, and a large empyema opened which extended forward to a depth of 8 inches, but was bounded externally by the lung which was completely adherent to the parietal pleura, and collapsed, dull, and silent.

Another rare position is between the base of the lung and the diaphragm; of this I have only seen one case. After a right-sided pneumonia, the temperature and condition of the patient pointed to empyema, but, though the lower half of the right chest was wanting in resonance, it was not as dull as in empyema, and redux crepitations could be heard practically to the base, but I found a dull and quite silent area about 3 inches broad over the lower ribs in the posterior axillary region. A needle inserted here withdrew pus, and Mr. Fletcher in operating found a largish empyema between the lung and the diaphragm, with the lung firmly adherent to the chest wall above it.

Abscess of the Lung.—Suppuration of Bronchial Glands.

Abscess of the lung is another complication. A soldier was admitted under me during the war with a very severe broncho-pneumonia mainly of the right side, tubular breathing being most marked between the middle of the scapula and its angle. On the thirteenth day he suddenly spat up about an ounce of blood, and the following day his sputum became most offensive. A small patch of cavernous breathing could be heard in the centre of the tubular area. A radiograph taken by Captain Morton showed a round abscess cavity surrounded by inflammatory thickening at the level of the sixth rib. He was treated by inhalations of creosote, carbolic, and iodine from a Burney Yeo inhaler for several hours every day, and made a good recovery. Results of lung abscess are not usually so satisfactory, as they are generally due to gangrene of a larger area than in this case, and the mortality is very high. Surgery so far has not been very successful in such cases.

Suppuration of bronchial glands is a very rare complication, of which I have only seen one case, the diagnosis being made by my father. A week after the subsidence of a very severe pneumonia in a boy, the temperature began to rise, and a paroxysmal cough came one, very like whooping-cough, but the spasms lasting very much longer, even two or three hours, and being only controllable by light inhalations of chloroform. Eating and turning on to the right side provoked attacks of coughing. Vomiting was frequent. This sort of cough strongly suggested enlargement of bronchial glands. After four days of this condition there was a slight rigor with a rise of temperature to 101·2° F. On auscultation tracheal breathing could be heard over the upper sternum, and distant tubular breathing in the right first space near the sternum. Next day the heart was displaced to the left, and there was dullness in the second space. The temperature was hectic for the next five days, then signs of fluid began to appear at the right base. This was found to be only serous on inserting a needle. On the tenth day after the rigor he suddenly spat up half an ounce of pus, and coughed up some more during the day. The temperature at once fell. The suppurating gland had evidently burst into a bronchus. The heart only slowly regained its normal position, and the tracheal breathing disappeared. The fluid at the right base became absorbed.

Other Complications.

Pericarditis also is a rare complication, in some cases pus forming in the pericardium. Ulcerative or infective endocarditis may be set up by pneumococcus after pneumonia. It may be subacute, the temperature only being above normal two or three times in a week, and there may even be no cardiac murmur or only a mitral systolic, but the pulse is always quickened, and the patient is pale, ill-looking, and breathless, and often complains of shivery feelings, though there are no rigors. After some months this may become acute and end with emboli in the brain. In other cases there may be continuous pyrexia, with frequent showers of small emboli in the lower legs and forearms, and occasional infarcts in the lungs and intermittent albuminuria. Dr. Helen Boyle and I had the satisfaction of effecting a cure in such a case over a year ago by numerous injections of antipneumococcic serum, continued in spite of severe anaphylaxis.

Jaundice of a non-obstructive type, bile persisting in the stools, sometimes occurs in severe cases. A croupous colitis, accompanied by diarrhœa, is described by Bristowe and Osler. Post mortem a thin, flaky exudate is found on the summits of the folds of mucous membrane. Peritonitis as a complication is very rare, though pneumonia following on a pneumococcal peritonitis is not uncommon. Otitis media, mastoid suppuration, inflammation of the antrum, and other sinuses may occur.

Meningitis is not often met with in adults, but is not altogether uncommon in young children. It is a general inflammation of the meninges of the whole cortex. The early diagnosis is not easy, but it should be looked for when there is much delirium, by bending the head forward to see if the chin will touch the sternum, and by testing for Kernig's sign. If there is any suspicion a lumbar puncture should be done. This complication is usually fatal, but I have cured two cases by frequent injections of anti-pneumococcic serum, daily lumbar puncture, and large doses of urotropin. In one of these cases the cerebro-spinal fluid resembled the pus from an empyema.

Treatment of Pneumonia.

In the treatment of pneumonia it is most important that the patient should be kept as quiet as possible, since auto-inoculation takes place on any movement.

Nurses should be told that washing must be limited to a minimum. Many years ago in a case of pneumonia I had the patient's temperature taken just before the morning's elaborate ablutions, and again half an hour after their completion, and there

was a rise of nearly a degree, with very distinct malaise. On the next morning the temperature was taken at the same times without any washing of the patient, and no rise was shown. Sponging without moving is comforting and good.

For the same reason examination by the doctor should be as little disturbing as possible; percussion should be very light. After the diagnosis has been made, it is unnecessary to listen to the backs unless there are signs of fluid. The chest should be examined as far back as the posterior axillary lines without moving the patient, and, as long as crepitations and breath sounds are heard there, no serious amount of fluid can have accumulated. In the old-fashioned lobar pneumonia, with constant temperature between 104° and 105°, a large ice-bag continuously applied over the site of the pneumonia undoubtedly does good. In other cases antiphlogistine is beneficial, or, if there is much pain from pleurisy, this may be preceded by a linseed and mustard poultice.

As to specific treatment, a vaccine, if of the right type of pneumococcus and the correct combination of germs, may be very useful, if given early in the disease; but it is not safe in the very poisoned cases with low temperatures, as the negative phase may be too much for the patient. After the second day vaccines are not likely to be useful, since pneumococci are then usually circulating in the blood, and, if live pneumococci going through the glands will not produce antitoxin, it is unlikely that dead ones will. In delayed resolution, when the physical signs are not clearing a week after the subsidence of the disease, autogenous vaccines are of great assistance, also after operation for empyema they hasten the cure.

Many years ago I was told of the merits of Pane's anti-pneumococcic serum by the senior physician of Frankfort Hospital. Up to 1917 it was the most valuable remedy, but in the influenza epidemic of the autumn and winter of 1918 it was apparently useless, as also were the English and American serums; but the Pasteur Institute in Paris had prepared a serum by inoculating horses with all the germs of the spring epidemic of 1918, and the results of its use were marvellously good. Twenty cubic centimetres, repeated in from 12 to 24 hours, is usually sufficient, but a third injection may be necessary. Dr. Pane has since then followed the lines of the Pasteur Institute, and his serum is now quite effective.

Medicinally aspirin, first recommended by Dr. Alfred Scott, is undoubtedly valuable, but the doses should not be too large. I once saw, in consultation, a girl, who, just after the crisis, with a normal temperature was suffering from intense dyspnœa. There were no signs of fluid in the chest, and the dyspnœa reminded one of the air-hunger of diabetes. I found that she had been given large doses of aspirin, and concluded that it was a case of acidosis. Bicarbonate of soda by the mouth and rectum stopped the dyspnœa in a few hours, and the child made a normal recovery.

Quinine, given with aspirin, is also helpful, and this especially in post-influenzal cases. I have had good results with the creasote and iodide mixture, but patients dislike it. Ipecac. and iodide may be useful in loosening expectoration. Oxygen should always be kept ready. As a sedative at night Dover's powder is one of the best. In cases of intense poisoning Warburg's tincture is very valuable given by mouth or rectum, as, besides being a bactericide, it is a strong stimulant. It must be given in an alcoholic solution, such as port wine, since water precipitates the resins and destroys its efficacy. Hyperpyrexia should be treated by ice sponging or packing, and by large doses of Warburg's tincture.

It is very important to watch the heart. In the early stages of lobar pneumonia, if there are signs of over-distension of the right side of the heart, such as duskiness of the face, and marked epigastric pulsation, six leeches over the site of the pneumonia will have a good effect. If the pulse-rate is above 100 digitalis should be given regularly, but not in very large doses, and if up to 120 hypodermic strophanthin. Camphor hypodermically is also very useful.

PNEUMOCOCCAL INFECTIONS: THE BACTERIOLOGICAL ASPECT.[1]

BY J. HENRY DIBLE, M.B., CH.B. GLASG., M.R.C.P. LOND.,
LECTURER IN BACTERIOLOGY, UNIVERSITY OF MANCHESTER.

I feel strongly that a consideration of the causal organism of pneumoccocal infection should be the first event in any survey of its effects in the body. I have no new facts to contribute to this discussion, but I want to put before you a view of the present position of the pneumococcal lesions in pathology in the light of recent work with which I am familiar, and, since it is not possible to cover more than a small portion of the field, to take up certain sides of the activities of the organism which especially interest me, and to introduce them as subjects for later discussion.

The pneumococcus is usually and classically described as a Gram-positive, lanceolate, encapsulated diplococcus. It further has the following properties. Growing upon serum agar, which is an excellent medium, it forms small discrete colonies notable for their translucence; often these have a ringed appearance which is characteristic of many, but not of all, strains. Upon blood agar it produces methæmoglobin and turns the agar green; some strains produce, in addition, hæmolysis. It is an active fermenter of sugars, especially raffinose and inulin, this latter character tending to differentiate it from most streptococci, and in bile or bile salts it undergoes solution. Further, it is pathogenic for mice, in which animals it occasions a fatal septicæmia. What I have so far described is the classical conception of the pneumococcus, but in one or another property it often fails to correspond to this; other nearly related organisms frequently show some of the features considered characteristic of the pneumococcus. Elsewhere I have endeavoured to show that classification in the streptococcus group, of which the pneumococcus is a member, cannot be arrived at by the consideration of any one single property—morphology, sugar tests, hæmolytic action, &c.—but that we can only give a name to any one member of this group by considering all its properties together—particularly the following, which serve best to differentiate it from the enterococcus and streptococcus groups, taking into consideration at the same time morphology and cultural characters.

	Heat Resistance, 15″ at 60° C.	Bile and solubility.	Inulin.	Mannite.
Streptococcus	−	−	−	−
Enterococcus	+	−	−	+
Pneumococcus	−	+	+	−

Where, in organisms that otherwise conform, these four characters are distributed in the way I have shown, then the differentiation of the organisms is as certain as it can be, and where three of them are in accord, even if the fourth is anomalous, it is *probable* that an organism must still be placed within the group to which a majority of these characters assign it. Having put forward a definition of the pneumococcus, I want to touch briefly upon the following points. Firstly, its serological types; secondly, the routes of infection by which it obtains access to the body; and, thirdly, the lesions which it produces.

Serological Types of Pneumococcus.

The idea of agglutinating pneumococci is no new one, but experiments upon these lines remained unconvincing until in 1913 Dochez and Gillespie, examining 62 pneumococci in the presence of two monovalent agglutinating sera which they had prepared, found that 61 per cent. were agglutinated by either the one or the other serum, and grouped the whole series in the following manner.

[1] The opening paper read at a meeting of the Manchester Pathological Society on Dec. 12th, 1923.

I give the original figures of these workers; later and larger results have somewhat modified their proportions.

	Per cent.	
Type 1	41	(Agglutinated by Type 1 serum.)
,, 2	20	(,, ,, ,, 2 ,,)
,, 3	17	(*Pneumococcus mucosus*: distinguishable culturally.)
,, 4	22	(The residue: not serologically a fixed type.)

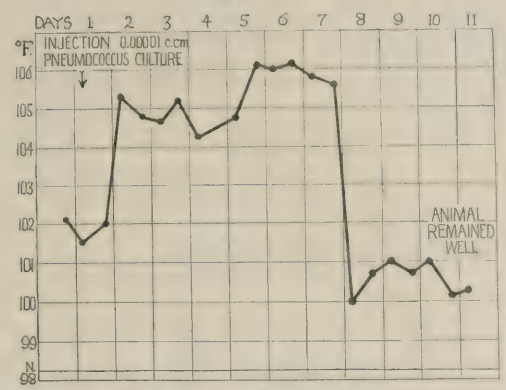
Such a serological grouping has been largely substantiated by animal experiments, the serum obtained by injecting an animal with group 1 coccus having considerable powers of protecting mice against infection with members of the first group. The same fact holds, but the efficiency of the serum is less marked, for group 2. Against group 3, which comprises organisms producing characteristic colonies and an especially dangerous type of pneumonia, an efficient serum could not be obtained, and in group 4, which is a residual class in which the majority of members are serologically independent, no single serum could be expected to prove efficacious against more than, at the very most, an extremely small number of strains.

The practical point which emerges from such a serological study is that the pneumococci fall naturally into a number of races which are serologically independent and specific, and, further, that antibodies, and consequently antisera, produced by means of members of one group are only potent therapeutically in infections by members of that group. Thus a specific serum which has a protective or curative value in group 1 infections is impotent against group 4 infections. The American work in this respect dominates the field, but although admitted in principle it is not universally agreed upon in detail. The French (Nicolle, Truche, &c.) deny the sharpness of the American divisions, insist on a much greater degree of overlapping than they allow, and hold that a similar overlapping exists in the protective power of sera when prepared from highly virulent strains, although admitting that these exert generally their maximum power against homologous organisms. The practical bearing of these investigations is upon the specific treatment of the disease, which will be dealt with fully by a later speaker.

Routes of Infection.

The lesions produced in the body by the pneumococcus are mainly those in the lungs, the meninges, and the abdomen. In the lungs the lesion is pneumonia; and in speaking of pneumonia I mean acute lobar pneumonia, a disease whose causal agent, in my limited experience, has invariably been the pneumococcus. I exclude from my contribution to this discussion broncho-pneumonia, which is a different disease and is not a specific infection. I do not propose to deal with the well-recognised pathological lesions of this condition, but only to allude to one or two of the more interesting problems which it presents. In the first place I wish to discuss the route of invasion of the lung. This has alternatively been described as by the air-passages and the blood-stream, and in reviewing the evidence we find many old facts and certain new ones. The old facts are these. In favour of blood infection we find the pneumococcus in the blood in a majority of cases of pneumonia, and I think that we can safely say that the organism is present in the blood-stream *at some time* in all cases of pneumonia. In the second place, certain cases have from time to time been cited in which pneumonia has definitely been a secondary event in the history of a pneumococcus septicæmia having origin in a lesion elsewhere. All that these facts go to prove is that the pneumococcus *can* spread into the lung when it invades the blood-stream. The real problem, however, is whether in the ordinary case the lung is invaded normally by the bronchial route, or whether the blood-stream is first invaded and the organism "electively" localised in a tissue which peculiarly favours its growth. The pneumococcus is normally an inhabitant of the mouth—an observation which goes back to Pasteur—but the type commonly found is generally the relatively avirulent Type 4; the more virulent Types 1 and 2 are rare in the normal mouth, although frequently present in cases of pneumonia. This puts the disease more than ever in the infectious category and opens up the question of whether pneumonia is not

FIG. 1.



Temperature chart of experimental pneumococcus pneumonia in a monkey (Cecil and Blake).

normally caught from another person rather than an autogenous infection, as has been widely held for many years. Given the presence in the mouth and upper air passage of an organism capable of causing pneumonia, we have to ask what is its subsequent path of advance, and by what means does it find its way into the pulmonary tissue? The matter has been considerably illuminated by some recent experimental work carried out by Cecil and Blake at the Rockefeller Institute, which has a very distinct bearing upon the problem. These observers studied at great length and in admirable form an experimentally produced pneumonia which they brought about by the intratracheal injection of quite small doses of virulent pneumococci. This was done by the introduction of a fine needle through the crico-thyroid membrane and

FIG. 2.

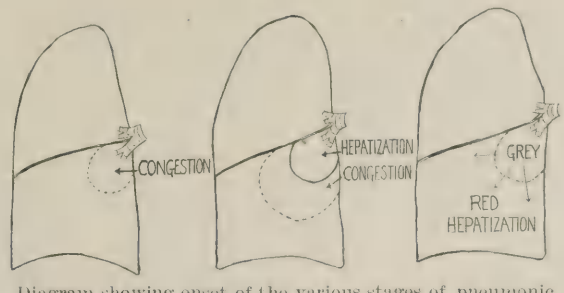


Diagram showing onset of the various stages of pneumonic consolidation and invasion of a lobe from the root zone.

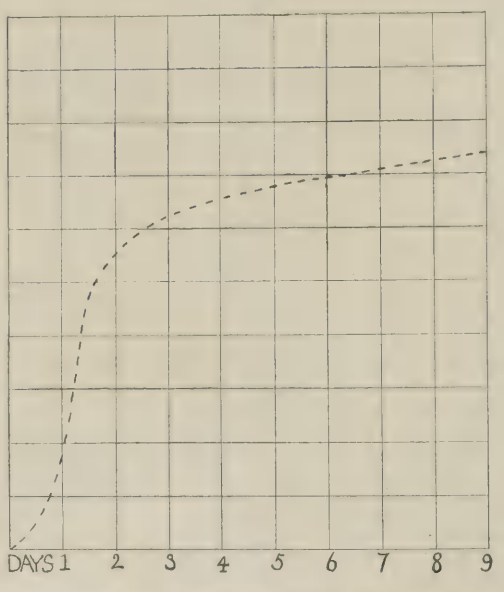
the injection of the organisms in varying doses made up to a total bulk of 1·0 c.cm.—a trivial procedure in itself.

They found that with certain doses pneumonia could invariably be produced, and that this experimental disease was lobar in type and in every way comparable to the human disease, often beginning with a rigor, running a course of continued pyrexia for a number of days with a temperature chart absolutely comparable to that of the human case, associated with a polymorph leucocytosis, and either ending by crisis or causing death (Fig. 1). They also found that by putting normal monkeys into small confined cages with such artificially infected ones the disease might be caught by the former, and was associated with the presence of pneumococci of the same type as that used to infect the experimental animal. The appearances of the lungs in these animals was strikingly similar to those seen in human cases. The importance of this work lies in

the following points. It proves conclusively, if proof be still needed, that the pneumococcus will produce lobar pneumonia, and the fact that the disease could be produced at will and with certainty gave the experimenters opportunities for studying stages in the disease which are only very rarely available in human cases. With regard to the route of infection, this work confirms the aerogenic theory, since other animals injected intravenously or subcutaneously developed not pneumonia but septicæmia, which was not accompanied by lung lesions. There still remains a gap in our knowledge concerning the mechanism by which, in human cases, the organisms pass from the mouth to the

FIG. 3.



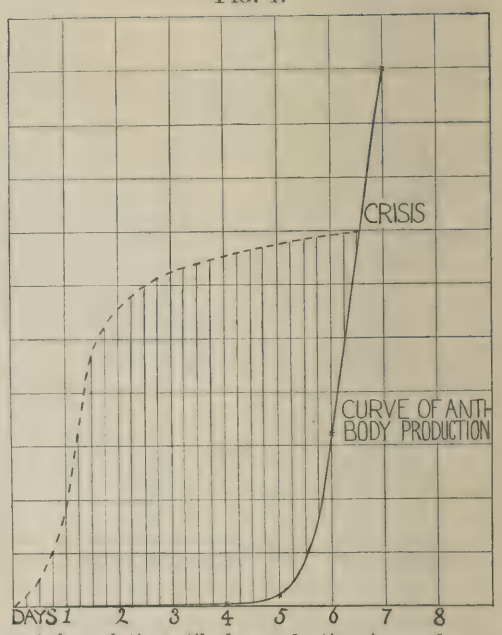
Theoretical curve of the rise and course of pneumococcal intoxication in pneumonia in a case not going to crisis by the end of the eighth day.

sublaryngeal region. Injection into the trachea caused practically invariably pneumonia, but spraying the mouth and pharynx by an emulsion of organisms was ineffective. In the work of Cecil and Blake it was also possible to study the course of invasion of the lung. The rapidity with which a whole lobe becomes consolidated has caused much speculation as to the mode of spread of the disease, and it has been asked if the infection involves in almost simultaneous fashion the whole of a lobe, or, alternatively, if to effect this rapid involvement lobar pneumonia may not have in its evolution a bronchial stage and be, in effect, a confluent broncho-pneumonia. The study of early lesions in apes shows that the disease spreads into the lung not along the air ways but eccentrically, from the root and main bronchus, and that in the early stages the organisms are not in the bronchioles and alveoli at all but are confined to the fibrous framework of the lung—perivascular and peribronchial areolar tissue, interlobular septa, and alveolar walls.

The Lesions Produced.

Thus, in its early stages the disease is *an interstitial inflammation* spreading outwards, fanwise, from the lung root. When, in common with all forms of inflammation, fluid and cells are poured out from the dilated vessels, these naturally accumulate in the alveoli, leading to red hepatisation, which follows the same line of spread from the hilum to the periphery (Fig. 2). It is only when the air sacs become filled with exudate that the pneumococcus grows out from the framework of the lung into the now consolidated air-spaces and appears in them. Grey hepatisation appears at about the fifth day; commencing in the portion of lung earliest affected, the root, it follows the same course of spread, and in experiments with apes it has sometimes been possible to find in an affected lobe a state of grey hepatisation at the hilum, of red hepatisation throughout the greater part of the lung, and of incomplete consolidation at the margins. We sometimes see the latter condition in consolidated lungs post mortem, but from a perusal of the findings I have been describing it seems that the disease spreads less rapidly through the lung in monkeys than it does in the human subject. The sharply lobar distribution is explicable, as it always has been for those who accepted the aerogenous theory, on anatomical considerations. The relatively avascular pleura opposes a pretty effective barrier to

FIG. 4.



Curve of hæmolytic antibody production imposed upon the theoretical curve of pneumonic intoxication The shaded area represents the degree and duration of the latter, and its rapid obliteration by the sudden formation of antibodies.

the direct and contiguous spread of inflammation, much as the dura often does under other circumstances. It is only after effective soldering of two lobes by plastic exudate, and inflammatory vascularisation of the opposing pleural layers, that one can conceive of a spread from lobe to lobe at a distance from the hilum. When this occurs, the infection may creep across the barrier and invade a contiguous portion of lung by continuity of tissue; here, of course, there is no outward spread from the hilum, such as I accept now as the ordinary mode of invasion of the primarily affected lobe.

Cause of Crisis.

One other interesting speculation upon which I should like to touch is the cause of the crisis. This has been variously attributed to a sudden development on antibodies; to an anaphylactic reaction (Truche); to a development of hydrogen-ion concentration in the diseased tissue incompatible with the life of the pneumococcus; and, by McLeod, to the production by the organisms of hydrogen peroxide, which ultimately reaches a concentration sufficient to destroy them. I cannot go over the arguments for or against these various views; my personal view inclines towards the antibody development theory. This, I am conscious, is a view at which gibes can readily be cast on account of the vagueness of our knowledge of antibodies, and I know it carries us perilously near to the conceptions of the older school of humoral pathologists. There are two outstanding facts which demand consideration; the first, which dominates the picture of crisis, is its time of occurrence, which is so regularly in the vicinity of the seventh day—the sixth to the eighth. The second fact is that the serum of

patients who have recovered from the disease can exert a definitely protective action towards mice, although no antibodies may be demonstrable by experiments in vitro. We are therefore, I think, entitled to assume the presence of some unrecognised antibody. Let us look at the condition of the patient. Pneumonia is a disease which develops rapidly, and once it is fully developed runs an approximately steady course over a number of days. I therefore suggest that the patient during this period is receiving a steady dosage of the poisons produced by the infecting organism, and that the cure of these, after a rapid rise, is maintained at a fairly steady level (Fig. 3); in the meantime the antibody production is slowly called into being by this fact. If we examine the course of development of easily observed antibodies in an experimental animal—e.g., the hæmolytic antibody—we find that after injection (or infection) the rise comes on gradually after a latent period, is slow in the beginning, and then gathers way with great rapidity. In a case where the response is good its curve is ascending in an almost vertical line somewhere about the sixth or seventh day. There is no reason to believe that the mechanism of production of antibody to the pneumonic organisms and its toxins should be a different one, and it therefore seems likely that the steady intoxication of a pneumonia is abruptly terminated by the steep and sometimes dramatic rise of antibodies which may be expected just at the time at which crisis takes place, and that where the curve of antibody rise cuts the curve of toxin concentration, there crisis occurs (Fig 4).

I have only touched upon the fringes of this fascinating subject, and even then upon only one of the types of infection which it includes. It has not been possible to deal with the infections of the peritoneum and meninges, both of which will, I hope, be dealt with in the course of the discussion.

THE TREATMENT OF ACUTE PNEUMOCOCCUS INFECTIONS OF THE RESPIRATORY TRACT.[1]

BY G. J. LANGLEY, M.D., M.R.C.P. LOND.,
PHYSICIAN, ANCOATS HOSPITAL, MANCHESTER.

I PROPOSE to limit my remarks within the very narrow compass of the acute respiratory infections due to the pneumococcus. And since this leaves a vast bulk of literature and work to be dealt with, I would further limit my observations to the treatment of acute respiratory infections by the pneumococcus.

Recognition of the Rôle of the Pneumococcus.

As long ago as 1874 it was pointed out by von Jurgensen that pneumonia was, in its course and character, an acute infection. Bacteria were first demonstrated in the sputum by Klebs, but Freidländer first described an organism which was regarded as the causative agent. This opinion was severely criticised by Baumgarten, and was quickly replaced when much more careful and generally accepted work was published almost simultaneously by Fraenkel and Weichselbaum. In 1880 and after Fraenkel's organism was found in other lesions than pneumonia. In the same year the pneumococcus was found in healthy saliva by Aufrecht, by Pasteur, and by Sternberg. These organisms were proved to be fatal to rabbits, but no pneumonic consolidation of lung was found in the animals. These findings, in conjunction with other facts, led to the belief that infection took place by direct inhalation of a normally existent organism of the upper respiratory tract, resistance being for some reason temporarily lowered. In 1884 Weichselbaum demonstrated the organism in the peripheral blood of patients with pneumonia, and prior to 1900 Silvestrini and Sertoli had recovered the pneumococcus from the blood-stream in 15 out of 16 cases, at the same time showing that this did not affect the prognosis.

[1] The second paper read at the meeting of the Manchester Pathological Society on Dec. 12th, 1923.

The recognition of the pneumococcus as the causative agent in pneumonia led directly to its recognition as the causative agent also in some of the complications of the disease—empyema, endocarditis, pericarditis, and arthritis. But in spite of this and of the concurrent development in the course of the disease, of nephritis, jaundice, and parotitis, the appreciation of pneumonia as a blood infection appears from the literature only slowly to have gained acceptance. It was taught that pneumonia was a focal disease with a general toxæmia, and it is still uncertain how widely acceptable is the view that pneumonia should be regarded as a blood infection with a focal involvement, precisely on all fours with typhoid. The point of view would appear to be important in the consideration of treatment.

Present Position of Treatment.

The early attempts to treat the disease along the lines of anti-sera were frustrated by the difficulties experienced by workers in their studies of the causative organism. Little if any reaction could be obtained by animal inoculation, except against the individual inoculum, and it was concluded that too many types of pneumococcus existed to make serum treatment a possibility. In 1913 Dochez and Gillespie published their study of pneumococcal classification by means of immune sera. By this means the organisms were divided into four groups, but not until the publications of the Rockefeller workers in 1917 did the classification bear any direct relation to the treatment of the disease.

The present position of this work is, I take it, somewhat as follows: The division of the pneumococcus into four groups is now generally accepted, except in France, where only three are recognised. Type 1 is accepted by all workers as a fixed type which produces a specific anti-serum, although this can only be accepted with certain reservations in view of Andrewes's recent work. Type 1 anti-pneumococcic serum is regarded by the Rockefeller workers as a specific against Type 1 pneumonia. This is accepted fairly generally in America, but with a good deal of reserve elsewhere. Glynn, in his 1923 report to the Medical Research Council, states that almost no evidence of the value of this treatment is available from English observers.

To determine, therefore, the desirability of trying this line of treatment in England, it would seem proper at the outset to consider some of the factors which must enter into a weighed judgment: (1) Incidence and mortality of pneumonia in England as compared with America; (2) incidence and mortality of Type 1 pneumonia in England as compared with America; (3) American statistics by workers other than those at the Rockefeller Institute of the success or otherwise attending this line of treatment; (4) experimental determination of the potency of the serum; (5) availability, dosage, and method of administration of the serum, with any dangers which may accompany its use; (6) any other line of treatment giving results as satisfactory and resting upon any sort of basis other than an empiric one.

At the outset it may be well to remember two fallacies which are extremely liable to affect such inquiries: First, the estimation of the value of a remedy is one of the most difficult of all problems. William Withering, in introducing digitalis to medicine in 1785, wrote: "It is much easier to write upon a disease than upon a remedy. The former is in the hands of nature, and a faithful observer, with an eye of tolerable judgment, cannot fail to delineate a likeness; the latter will ever be subject to the whims, the inaccuracies, and the blindness of mankind." Secondly, although we may agree with Sancho Panza that there is little to be gained by looking for this year's birds in last year's nests, yet it is equally true that we are very liable to believe the birds to be flown when in reality the eggs are addled.

Mortality.

The mortality for most acute infective diseases has gradually diminished under the improved hygiene of

the past few decades. The table shows these facts for England and Wales. In 1919 the total deaths from pneumonia, as given in the Registrar-General's report, was 38,984, yielding a death-rate of 105·8 per 100,000 (Table I.). In America the corresponding death-rate was 149·8 per 100,000. It would not appear that any further figures are required to demonstrate the very present importance of the question of the treatment of pneumonia. The title of Captain of the Men of Death, given to tuberculosis by John Bunyan, was transferred from that disease to pneumonia by William Osler. Cole states that in England, France, and America probably one-tenth of all deaths are due to acute respiratory diseases. Often enough this is merely a terminal event, but apart from these, many are wiped out at the maximum of their economic efficiency. Shattuck and Lawrence, analysing 2882 cases from the Massachusetts General Hospital, concluded that there was a 10 per cent. increase of case mortality for every decade after the age of 20.

Type Incidence.

Polyvalent and other sera have from time to time been introduced for the treatment of pneumonia, but it appears that they have failed to satisfy bacteriological tests with the exception of that prepared by Trouche. The Rockefeller workers only offer a serum against type 1 pneumococcus. It therefore becomes important to find the percentage incidence and mortality of type 1 pneumonia so far as figures are at present available.

TABLE I.—*Crude Mortality Rate per Million Living.*

Year.	Typhoid.	Phthisis.	Pneumonia, excluding influenza.
1861–70	—	2590	990
1871–80	321	2231	937
1881–90	199	1810	1034
1891–1900	175	1418	1214
1901–1910	91	1143	1254
			Death-rate from pneumonia per 100,000.
1919 England and Wales ..			105·8
1919 America			149·8

Tables II. and III. show the incidence and mortality of the various types of pneumonia in America and part of Europe. For the bulk of my figures I would acknowledge my indebtedness to the very interesting report to the Medical Research Council by Prof. E. E. Glynn, of Liverpool, and his co-workers, as also for the excellent bibliography. It is at once noticeable how largely the American figures bulk in all these records, but a great deal of similar work has been done by Lister and others among the Rand miners, of whom pneumonia has been and still is so great a scourge. From the tables shown it would appear that one-third of the English and American cases are due to type 1 pneumococcus, and taking the 1919 figures for England, Glynn estimated that in that year 32,000 people contracted type 1 pneumonia, and 8000 died from it. So that there would appear to be quite sufficient annual material to justify the use of the serum here as in America.

TABLE II.—*Lobar Pneumonia.*

—	Type 1.		Type 2.		Type 3.		Group 4.	
	Inc.	Mort.	Inc.	Mort.	Inc.	Mort.	Inc.	Mort.

Efficiency of the Serum: Experimental.

As the guinea-pig is the final court of appeal in tuberculosis, so is the white mouse in pneumococcal infections. The reaction in the latter is to some extent both qualitative and quantitative, and the minimal lethal dose of a culture can be determined with moderate ease. If antipneumococcal serum can reasonably be expected to produce any curative effect, it should antagonise a high multiplication of the minimal lethal dose. The Rockefeller workers found that they could produce antisera to types 1, 2, and 3, but they failed to do so for group 4, except for individual members of that group. Further work led them to the conclusion that their antisera for types 2 and 3 were unsatisfactory, but they found that a serum could be produced, 0·2 c.cm. of which would protect a 20 g. white mouse against 10,000 M.L.D. of type 1 pneumococcus. Other observers appear to have obtained much the same results. In 1920 Cecil and Blake published a most interesting series of articles, in which they showed that constant results could be obtained by intratracheal injections of virulent pneumococci in monkeys, and that the disease so produced ran a course exactly comparable with pneumonia in the human subject.

Experiments were then made with type 1 pneumococcus, pneumonia being produced with an amount of inoculum well above the M.L.D. for the monkeys used. Antipneumococcic serum type 1 obtained from the New York State Board of Health was given on various days of the disease. Four examples are extracted on Table IV. to show the type of result obtained. These would appear to be as striking as any serological treatment could well be, but in reading their protocols one is constantly struck also by the certainty and rapidity with which the organisms disappear from the blood-stream. There is no record of any untoward results from the quantity of serum administered. The average weight of the animals was one-sixteenth the weight of the average human being, and it is supposed, therefore, that to obtain the same results clinically sixteen times the doses here shown would be required.

Efficiency of the Serum: Clinical.

In the estimation of the efficiency of any serum treatment many factors must be considered, and the numbers available for judgment are insufficient to come to any real conclusion. Table V. gives some indication of the results; more than half the cases are recorded by the Rockefeller workers, and all the sera, so far as I have been able to find, came from that source. We do not know whether the average age of the untreated cases would be identical with that of those treated, neither do we know the day of disease upon which the serum was given. Although the sex incidence of pneumonia is as 3 to 1 in favour of males, yet the mortality is considerably higher in females. All these and a host of other factors will occur to each one of us, making the smallness of the data a very considerable bar to their ready acceptance. More particularly is this the case when we remember that the mortality from pneumonia in the pre-war German Army showed much smaller figures than those now given by the Rockefeller workers.

Clinical findings have been published showing the rapid disappearance of the pneumococcus from the blood-stream as the result of suitable serum treatment; findings exactly comparable with those of Cecil and Blake, but the value of negative findings in blood-culture work would appear to be very problematical.

TABLE IV.—*Results Obtained after the Use of Antipneumococcic Serum Type 1.*

Tables VI. and VII., copied from Locke's critical review of this work appears to carry with it some conviction in spite of the very small numbers, especially as it was produced under controlled conditions; for every case treated by serum one was also treated without serum.

Availability.—In looking through the present literature it appears that almost all the published results of serum treatment have been attained from that issued by the Rockefeller Institute. Type I anti-pneumococcic serum is now, however, a British product, can be readily purchased, and is standardised to the Rockefeller standard, but I know of no clinical records of its use. At the same time there would seem to be no reason why it should be any different from the older serum.

Dosage.—Speaking broadly, it may be said (1) that the serum should be given intravenously and slowly by a gravity method; (2) that the first dose should be 100 c.cm.; (3) that this dose should be repeated every eight hours until a favourable result is attained; (4) the average dose required is 250 c.cm., but in severe cases four times that amount may be necessary. Cecil and Blake undertook their work largely because they considered that physicians were unduly sceptical of the value of the serum and that when used, frequently it was given too late in the disease and in too small doses. It is probably as unfair to judge of serum treatment when given late in the disease as it would be to judge similarly of antidiphtheritic serum.

Dangers.

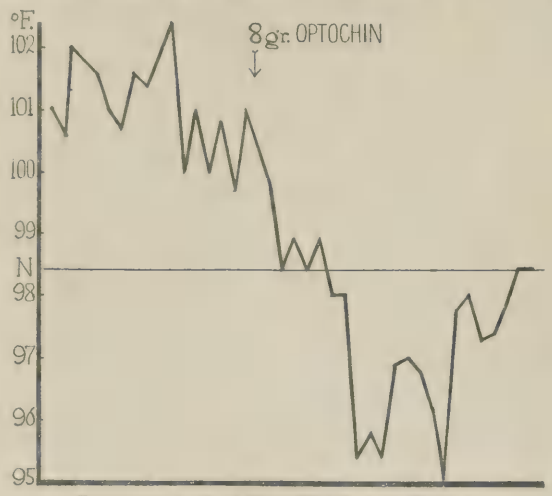
In looking through the recorded cases there appears to be a very real danger of serum reactions of two varieties: (1) An immediate reaction in the nature of anaphylactic shock, which can to some extent be countered by ten minims of one in a thousand adrenalin solution, or avoided by slow and gradual desensitisation; (2) a later reaction occurring around the eighth day and showing urticaria, arthritis, and pyrexia. It appears that in some cases this temperature reaction may last a long time, and may be difficult to differentiate from a continuance or a complication of the original infection. In this connexion it should be remembered that there is reason to expect serum sickness in the very type of patient for whom this treatment would seem most urgently needed. The man in the prime of life to-day has almost certainly been in the army, and is therefore quite likely to have had one or more injections of prophylactic antitetanic serum during his war service. The proportion of such in the adult male population to-day must be considerable, and they therefore constitute a very real danger. So that, prior to administration, it would seem wise to inquire carefully as to previous dosage with any horse-derived serum and also to inquire for a history of asthma.

Other Treatments.

In 1911 Morgenroth and Levy introduced the drug ethylhydrocuprein, a derivative from the quinine group, under the name of optochin, and claimed for it a sterilising power against the pneumococcus of a very high order. In 1912 Wright investigated these claims, and concluded that they were well founded. A series of clinical studies were made by Moore and published in 1920. A good deal of work has been done on this quinine derivative which goes to show the following points: (1) That its activity is much greater against the pneumococcus than against any other organism (so far is this the case that Moore suggests its use as a test for the pathogenic pneumococci); (2) that it will inhibit the growth of the pneumococcus in vitro in dilutions as high as one in a million; (3) that in experimental mice or rabbits it is capable of protecting against a hundred minimal lethal doses of virulent pneumococci; (4) that its action is best seen when given under conditions of slow absorption, and is too evanescent to produce good effects when given intravenously; (5) that when given in conjunction with a homologous antiserum it is capable of multiplying the effect of that serum by 50; (6) that it acts equally efficiently against all types of pneumococci, including *Pneumococcus mucosus* 3; (7) at the same time it possesses a very definite toxicity, and it is possible to kill the animal in attempting to cure the disease.

Moore and Chesney published in 1923 a report on the use of this drug in pneumonia. They state

that in 75 cases no definite therapeutic effect could be shown, but that 12 per cent. of their cases showed amblyopia, three mild in degree and six severe. All those who survived the pneumonia recovered their sight. They attribute failure to the toxicity of the drug, which shows toxic effects before a pneumococcidal concentration has arisen in the blood. It is stated that no ocular signs have been seen so long as the dose given does not exceed 24 gr. The temperature chart here given shows the result of one dose of



Four-hourly chart from fifth day of disease.

8 gr. given to a recent case which was not doing well; whether the marked subnormal temperature was post, cum, or propter is very doubtful, but the crisis was certainly accompanied by much more shock than usual. No data have been found for treatment with serum and optochin.

Returning again to the treatment of pneumococcal infections by homologous antisera, the question of determining the type of organism concerned must be considered from the point of view of the ease or difficulty with which this may be done. Antisera may now be freely purchased for this grouping; they can, however, scarcely be called "high-titre sera," for their titre is very low, and this materially diminishes their use, and one can only hope in the future that much higher titres may in some way be obtained.

There are two methods of grouping which may almost fairly be called clinical, in that they may be applied at the bedside in a short space of time.

(1) The urine is said to contain a body which by interaction with the specific serum yields a precipitate only for the group to which the infection belongs. The clear filtered or centrifuged urine is added to the undiluted high-titre serum, a precipitate indicating a positive result.

(2) Since bile solubility is one of the bacteriological tests for the pneumococcus, it follows that the organism may be extracted from sputum by that means. One per cent. taurocholate solution may be added to pneumonic sputum in equal volume, and the whole thoroughly shaken for some minutes. The mass is now filtered through ordinary filter-paper, and a precipitin reaction may be carried out in a piece of narrow-bore glass tubing with a teat on the end. In this way a rough grouping may be rapidly done against the undiluted type sera, although the lowness of the present British sera must delay the result. Glynn in his work found a similar procedure most useful and trustworthy, but he was using the Rockefeller sera.

To the ordinary bacteriological processes in connexion with the pneumococcus, Dr. Dible has already referred, but it is manifest that if the pathologist is to coöperate adequately with the clinician in this matter of grouping, the time occupied in investigation must be reduced to a minimum. It is in this respect that the white mouse method is so valuable, particularly if the peritoneal exudate be used for direct agglutination, as the time occupied would be measured in hours only.

Blood-culture has been found to give about 50 per cent. of positive results, and Rosenow considered that the fourth, fifth, and sixth days were the most likely; but lung puncture, used largely by French in France during the influenza pandemic, would appear to be quite safe, to involve the patient in but little suffering, and to give a very high percentage of positive results. This would appear for many reasons to be the method of choice, to which view Lister in South Africa also testifies. By either of these methods a pure culture is likely to be obtained, which is easy to agglutinate later.

I take it as an axiom nowadays that no remarks on the treatment of an acute infection can be regarded as complete without some consideration of the carrier problem. It is stated that 80 per cent. of all lobar pneumonias are due to one of the three fixed types of pneumococcus. On the other hand, 90 per cent. of pneumococci recovered from the bucco-respiratory tract of healthy individuals belong to group 4. Similar investigation of pneumonia contacts shows a very high percentage of pneumococci belonging to the type with which contact has occurred, as was shown by the examination of nurses, orderlies, residents, and physicians who were working amongst the disease. The carrier state of recovered pneumonia cases has been shown to persist for periods varying from 28 to 90 days, and it is well recognised that the virulence of the pneumococcus can be materially raised by animal passage.

Conclusions.

It has been my endeavour to lay before you some data upon which the following theses may perhaps be supported: (1) Pneumonia is an acute general infection; (2) its annual death-roll in our own country is sufficiently high to merit not only careful attention but furious thinking; (3) a greater statistical knowledge is more than desirable; (4) bacteriological investigation is not only the road to increased knowledge but also the key to treatment; (5) there is sufficient evidence to justify the statement that serum treatment should be instituted in suitably typed cases as early as possible in the disease, should be given in suitably large doses, should be repeated every eight hours, and should be persisted in; (6) optochin in non-toxic doses merits a further trial on the grounds of experimental data; (7) without the aid of one or both of these methods we are left with a merely expectant routine, creditable enough in the days of Hippocrates, but scarcely justified in the light of such masses of evidence as modern research has placed at our disposal.

DIABETIC COMA WITH ANURIA.

BY C. G. IMRIE, M.D. LOND. (ONT.),
LECTURER ON PHYSIOLOGY, UNIVERSITY OF SHEFFIELD;
AND
E. F. SKINNER, M.B. CAMB., F.R.C.P. LOND.,
ASSISTANT PHYSICIAN, SHEFFIELD ROYAL HOSPITAL.

A CASE of diabetes mellitus in coma, associated with complete anuria, provided the opportunity of observing the action of insulin upon the intermediary metabolism in diabetes under conditions where the excretory function of the kidney was in total abeyance, and therefore playing no part, in so far as that function is concerned, in the regulation of the chemical composition of the blood. (Experimentally, the condition might be simulated in a partially depancreatised animal by ligating the renal arteries and inducing coma by an appropriate diet.)

The observations made in this case, although by no means complete, are of considerable interest, for not only do they reveal what marked changes in the blood may be effected, independent of renal excretion when insulin is administered in diabetes, but also they show that the toxæmia associated with total suppression of urine does not inhibit the action of

insulin as do certain toxæmias, especially those of pyogenic origin.

Clinical History.

J. C., aged 60 years, a metal-smith, was admitted to the Sheffield Royal Hospital, under Prof. Arthur Hall, on May 30th, 1923, in a comatose condition, and the following history was obtained from his wife:—

The subject of diabetes for six years, he had been successfully treated by dieting during the last two, attending hospital as an out-patient. He was an intelligent man, and had been in the habit of testing his own urine from time to time, and on the appearance of sugar had abstained from all food until sugar-free. His diet during these two years had consisted of vegetables, eggs, bacon, and gluten bread. Ever since his illness began he had been troubled with constipation, but about Christmas, 1922, this became more pronounced, and he began definitely to fail, suffering from polyuria, which necessitated his rising frequently in the night, and great thirst. He also began to lose weight.

He was admitted to the wards at 1 P.M., and his condition was as follows: Dyspnœic but not hypernœic, pulse regular. Very thin and emaciated, lying with limbs still and rigid in a flexed position. They can be extended with difficulty. He is very drowsy, cannot answer questions, and seems unconscious of his surroundings, though he moves away from the prick of a pin. Eyes react normally to light, though both pupils are rather small. There is no paralysis of the ocular muscles, nor any retinal changes, his discs appearing quite normal. The tongue is dry and coated, and the breath smells strongly of acetone. There is nothing abnormal on abdominal examination. No paralysis of limbs and the superficial and deep reflexes appear to be normal. A few râles are audible at both lung bases and there is a faint systolic murmur heard over the præcordium.

It was clear that he was in a state of coma, and immediately he was ordered the usual routine treatment of soap enema, followed by saline enema, and hot water by mouth. At 6 P.M., as he had passed no urine, a rectal examination was made, which disclosed a moderately enlarged prostate, in consequence of which a catheter was passed but no urine was obtained. The blood pressure estimation gave the following figures: Systolic B.P., 105; diastolic B.P., 70. The blood examination showed: Blood-sugar, 0·957 per cent.; plasma bicarbonate, 15·7 vols. per cent.; ketone bodies, as acetone, 59·13 mg. per 100 c.cm., plasma; non-protein nitrogen, 110 mg. per 100 c.cm.

Treatment.—The treatment he received is summarised as follows:—May 30th: On admission, 1 P.M., enema, and hot water by mouth; at 6 P.M. and 9 P.M., insulin 20 units; at midnight, insulin, 20 units, glucose, 10 g., per rectum; May 31st: 4 A.M., insulin 20 units. By this time he was quite rational though still anuric. 10 A.M.: Pilocarpine 1/3 gr. produced profuse sweating; during the forenoon hiccough and vomiting began. 12 noon: Digitalis 1/100 gr., strychnine 1/60 gr.; 2 P.M., pituitrin 1 c.cm.; 4 P.M., insulin 20 units. In spite of hot packs, &c., he remained anuric and his condition steadily grew worse until death, which occurred on June 2nd, at 5 A.M.

Autopsy Report.

At the post-mortem examination many old adhesions were found on both pleuræ, with some basal œdema of both lungs. The kidneys were small and œdematous, and showed signs of chronic interstitial nephritis, the capsule being adherent. The bladder was small and contracted, and contained about a drachm of urine. The head of the pancreas appeared hard and fibrotic. There was generalised marked arterio-sclerosis throughout the body.

Microscopic Examination.—Liver: A slight early passive congestion is present and the liver cells contain a minute amount of bile pigment. No cirrhosis present and bile-ducts healthy. Kidney: Shows the typical "granular" appearance, with alternating markedly and slightly sclerosed areas. Hyaline casts are present in some of the tubules, but the tubules show no acute nephritic changes, though post mortem autolysis is present in moderate amount. Atheromatous changes, though present in some of the vessels, are by no means marked, whilst a trace of passive congestion is seen. Spleen: Shows some increase of the fibroblastic elements of the stroma. A few small recent hæmorrhages are seen in the section, as also small groups of cells containing pigment which appears to be hæmatoidin. The Malpighian corpuscles are normal. Pancreas: Sections from various areas of the pancreas have been examined. Some slight chronic fibrotic changes are seen about the ducts, whilst the alveolar portion of the gland is normal, save that the islets of Langerhans are practically unrepresented in the sections.

The blood-sugar was determined by the method of Folin and Wu.[1] At 5.30 P.M. on the day of admission it was 0·957 per cent. This is the highest value ever obtained in this hospital (higher values have been reported by Joslin.[2] who records a case with blood-sugar of 1·37 per cent. 12 hours before death). By midnight it had fallen to 0·56 per cent., and at 9 A.M. next day it reached 0·247 per cent. Thus in 15½ hours, during which time 80 units of insulin had been injected, the glucose was reduced to 25·8 per cent. of its former concentration. Assuming the blood volume in this patient to be 5 litres, and that it remained the same, there were about 35 g. less glucose in the circulating blood than before the exhibition of insulin. Of course, the actual amount of glucose utilised was considerably greater than this, for other body fluids would be in equilibrium with the blood as regards their glucose content. Since none was excreted by the kidneys, the glucose must have been oxidised, polymerised into glycogen, or converted into fat.

The Plasma Bicarbonate.—When the concentration of sugar in the blood was highest the plasma bicarbonate was 15·7 vols. per cent. This showed a very marked reduction (the normal average value being 60 vols. per cent.), and indicated a severe acidosis. The next day it had risen to 39 vols. per cent. The acetone bodies in the blood were determined by the method of Van Slyke and Fitz.[3] When the plasma bicarbonate was 15·7 vols. per cent. the total acetone bodies, expressed as acetone, were 59·13 mg. per 100 c.cm. of blood plasma. The next morning the value fell to 26·42 mg., and at 5 P.M. the same day reached a value of 6 mg. per 100 c.cm. of plasma. While the patient was in coma it was impossible to obtain a sample of alveolar air, but a sample obtained at 1 P.M. on the day following the beginning of insulin treatment had a carbon dioxide tension of 34·7 mm. Hg.

Remarks.

The changes thus observed are those which accompany the successful treatment of diabetic coma with insulin. The remarkable feature in this instance is that they occurred quite independently of renal excretion, for though the kidney was playing no part in the removal of glucose and acetone bodies from the blood, or in the regulation of the acid-base equilibrium by the excretion of an acid urine, an adjustment toward the normal was nevertheless brought about to such a degree that the patient emerged from the coma. It would seem that this must have been due to the oxidation processes in the tissues. With the utilisation of glucose there would be oxidation of the ketone bodies, with a liberation of bases and a corresponding diminution in the acidosis.

Such an assumption receives support by the following considerations. The ketone bodies in the blood, expressed as acetone, were 59·13 mg. per 100 c.cm. just before the insulin treatment was begun. By the next afternoon they had decreased to 6 mg. per 100 c.cm. Therefore, from every 100 c.cm. of blood 53 mg. of ketone expressed as acetone had been removed. Assuming that the ketone bodies were present in the form of β-hydroxybutyric acid, then from each 100 c.cm. of blood 96·89 mg. of this acid which would require 21·42 mg. of the base sodium to neutralise it were removed. With the oxidation of this acid the base would be liberated and accordingly increase the plasma bicarbonate, for the carbon dioxide tension of the blood is such that all the base available after the more highly dissociated acids are neutralised is converted into the bicarbonate. 21·42 mg. of sodium are capable of combining with 41 mg. or 25·7 c.cm. of carbon dioxide as the bicarbonate. Were this the only reaction taking place in so far as the oxidation of the β-hydroxybutyric acid is concerned, the plasma bicarbonate should increase 20·87 vols. per cent. As a matter of fact, it did increase from 15·7 to 39—that is, 23·3 vols. per cent. The non-protein nitrogenous constituents of the blood were increased. Twenty-four hours after the onset of the anuria 110 mg. per 100 c.cm. were present in the blood. Their value rose to 117 mg. on the following day and fell to 107 mg. before death. These values are similar to those observed in uncomplicated cases of suppression. In this case, with the chronic changes observed in the kidney at autopsy, it is quite possible, in fact likely, that the high non-protein nitrogenous content existed some time before the onset of the diabetic coma or the anuria.

The plasma chlorides were determined by Whitehorn's[1] method and showed only a very slight diminution. The values obtained were as follows: May 30th, 1923: 4 P.M., 0·465 per cent.; 6.15 P.M., 0·458 per cent.; 31st: 10 P.M., 0·439 per cent.; June 1st: 10 A.M., 0·420 per cent.; 4.30 P.M., 0·406 per cent. During the two days the value decreased about 13·7 per cent. of the original concentration. This may have been the result of blood dilution, but no hæmoglobin estimations were made at the time to determine if such dilution were taking place.

Our thanks are due to Prof. Arthur Hall for permission to observe and record this case.

THE INTERNAL SECRETION OF THE TESTIS.

BY KENNETH M. WALKER, F.R.C.S. ENG.,
HUNTERIAN PROFESSOR OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND; SURGEON IN CHARGE OF GENITO-URINARY DEPARTMENTS, ROYAL NORTHERN HOSPITAL, AND THE MILLER HOSPITAL FOR SOUTH-EAST LONDON.

ALTHOUGH the effects of castration have long been known to the world, only within the last half-century has it been realised that these effects are due to the body having been deprived of an internal secretion that is vital to the development of the secondary sexual characters. The actual date at which it may be said that the doctrine of the internal secretion of the testis was born was 1889, when Brown-Séquard described before a meeting of the Société de Biologie the results of his experiments upon himself with subcutaneous injections of fresh orchitic extract. This lecture not only established the fact that the testis had an internal secretion, but also laid the foundations of the whole conception of internal secretion, a conception which may have been hinted at by Berthold but had never before been clearly enunciated. To physiology this advance opened up a fruitful field for investigation, and to medicine it supplied an entirely new therapeutic weapon. Although the centre of interest afterwards shifted from the testis to the other endocrine glands, mainly on account of the greater possibilities that they offered in the way of organotherapy, the fact that it was Brown-Séquard's researches that made possible the subsequent triumph of thyroid therapy lends to the subject of the internal secretion of the testis a special interest.

But quite apart from its importance in the history of organotherapy there is attached to this subject an interest of more recent date due to the work of certain modern researchers, who have claimed that by employing means to increase the internal secretion of the testis it is possible not only to make good the defects of eunuchoidism but also to attack the symptoms of old age itself. I refer particularly to the work of Steinach and Voronoff. It may, therefore, not be out of place to review in the light of modern knowledge the whole subject of the internal secretion of the testis and to examine what means are available for augmenting the internal secretion of the testis, and what bearing these methods may have on the problem of old age. But before dealing with these problems it will be necessary to consider briefly certain questions connected with the origin, mode of action, and nature of the internal secretion of the testis. In seeking answers to the questions discussed in this preliminary article, it will be profitable to draw upon stores of knowledge amassed by workers in other branches of science, notably in the realms of biology and comparative anatomy. Biological problems will, however, only be dealt with in so far as they have a direct bearing on the subject under consideration.

The Results of the Removal of the Gonads.

The removal of the testes or ovaries has a profound influence not only on the development of the sexual apparatus, but also on the growth of the individual, on his metabolism, and even on his psychology. Most marked, however, is its effect on the development of the characteristics of sex and more particularly of those secondary characters which, although not essential to reproduction, are contributory to that act. Amongst these secondary characters of sex are the female breasts, the accessory sex glands, such as the prostate and vesicles, and the male weapons of offence and defence—e.g., the antlers of the stag, the spurs of the cockerel, &c.

It is important to remember that the severity of the effects of castration will depend on the age at which the operation is effected. Although definite changes occur, particularly in metabolism, and in the accessory sex glands, as the result of the removal of the testes from a mature individual, the outward effects of the operation are far less striking than when it has been performed in early life before the development of the secondary sex characters. In the latter case not only do such organs of sex as the prostate and vesicles fail to develop, but the whole growth and mentality of the individual is influenced so that he becomes easily recognisable from the normal male. But even if the removal of the testes be effected early in life the suppression of the secondary characters of sex is never complete. In the eunuch there appears a beard, although a sparse one, and that essentially male characteristic the margo supraciliaris is never suppressed. Moreover, if the testes and ovaries be removed from a young male and female of the same species, the adult that results is not identical in the two cases, even apart from the distinctive primary organs of sex. Differences will always be found in the general build of the two sexes, however early removal of the gonads has been practised. In other words, the tissues when deprived of the directing influence of the sex hormone still continue to develop to some extent along the original lines. It is doubtful whether complete suppression of the secondary characters of sex would be brought about even could the testes be removed very early in fœtal life, soon after their differentiation in the primitive genital trace. In this connexion the work of Meisenheimer and Kopec on insects is of special interest. These observers found that the removal of the gonads from the young larvæ of the gipsy moth (*Lymantria dispar*) was absolutely without effect on the development of the male and female adult characteristics. In their later experiments on the larvæ of the same moth they succeeded in grafting ovaries into males and testes into females, the transplanted organs persisting and sometimes becoming connected up with the genital ducts, the testis with the oviduct, and the ovary with the sperm-duct. Even in these cases the moths, on hatching, had the characteristics and instincts of the sex to which the larvæ belonged before operation, so that a male moth containing ovaries would pair readily with a normal female, and a female with grafted testes behave in accordance with its original sex when in the presence of a male.

In contrast to this may be cited the experiments of Steinach and Voronoff, who found that by cross grafting of ovaries and testes each sex could be made to assume to some extent the characters of the other. For example, Voronoff by grafting a testis into an ovariectomised goat produced horns resembling in size those of the male rather than of the female. Similarly, Steinach by means of ovaries implanted into a castrated male guinea-pig caused a hypertrophy and activity of the mammary glands of that animal. However, even in these cases a careful examination would reveal differences in structure sufficient to show that the animals did not correspond to the sex of the glands with which they had been grafted.

It would appear, moreover, that the dependence of the secondary sex characters on the gonads varies in different species, so that the results of castration are more striking in some animals than in others. Further, there is definite evidence pointing to the fact that there is a difference in the control exercised by the gonads in the case of the two sexes of the same species,

[1] Whitehorn, J. C.: Jour. Biol. Chem., xlv., 419.

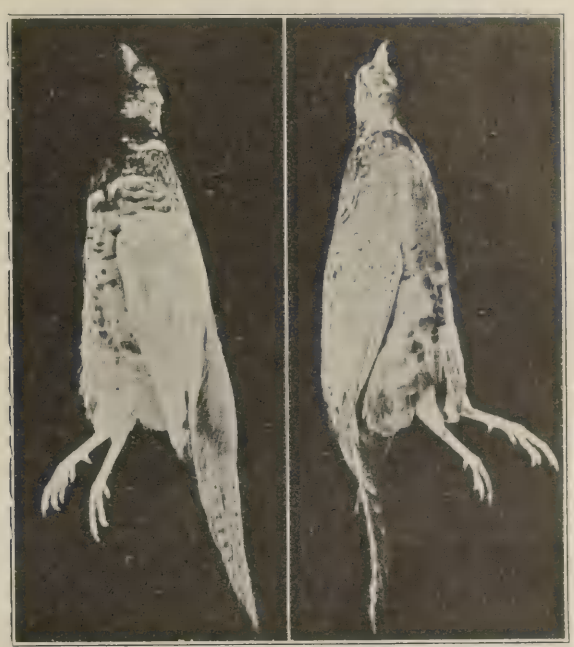
castration having a greater effect on the male in one species and on the female in another. Amongst fowls, for example, castration of the male results in the comb remaining small, the spurs poorly developed, and the male instincts suppressed. The plumage is, however, but slightly affected by the operation, so that the capon outwardly resembles a cock much more nearly than a hen. These changes may be summarised by saying that in the case of a cockerel the result of castration is infantilism. Removal of the ovary from a hen, on the other hand, causes the hen to assume to a very large extent the characters of the cock. The comb grows in size, and, what is more remarkable still, the plumage takes on to a great extent the characters of that of the cock. In other words, the result of castration in the case of the hen is not infantilism but masculinisation. The tendency shown by old hens in whom ovarian activity is on the wane to develop the attributes of the cock has indeed long been known by poultry breeders, and F. A. E. Crew has published an extremely interesting example of a transformation that occurred in a hen whose ovaries had been destroyed by tuberculosis. In this case the hen developed not only the plumage, crests, and spurs of the male bird, but also its aggressive nature, the power to perform the sexual act, and to fertilise eggs. Subsequent examination showed that the disease of the ovary had so altered the metabolism of the fowl that conditions favourable to the differentiation and growth of spermatic tissue had been created, with the result that new sex cords had been formed by the germinal epithelium. A complete sex reversal had therefore taken place. Goodale has made similar observations concerning the effect of removal of the gonads in the case of ducks, and has shown that whereas no alteration occurs in the plumage of the castrated male, removal of the ovary from the female causes the duck to assume gradually the typical plumage of the drake. It would seem, therefore, that in the case of birds removal of the ovaries has a more profound influence than removal of the testes. In mammals, on the other hand, the converse would appear to be true, removal of the testes having more effect on the development of the male than removal of the ovaries on that of the female. In human beings no direct observations are available, owing to the fact that removal of the ovaries early in life has very seldom been carried out. However, there is reason to believe that in man, as in other mammals, removal of the testes is more far-reaching in its results than is removal of the ovaries. Destruction of the testes early in life, either by operation or by disease, leads to the production of a eunuch who as regards certain characters, for example the development of subcutaneous fat, the growth of the breasts, and the distribution of the pubic hair, approaches the female. Disease or congenital deficiency in the ovaries is, however, not productive in the human being of male characteristics, but of infantilism. Masculinity in girls is not usually the result of disease of the ovaries, but of the suprarenals; new growths of that gland, as Blair Bell has emphasised, brings about precocity in boys and masculinity in girls.

These interesting differences in the response of the tissues to endocrine influence in the case of the two sexes all serve to emphasise the fact that the action of the sex hormone is not so simple as would at first sight appear. The development of secondary sex characters can no longer be regarded as resulting simply from the action on the tissues of a hormone elaborated in the gonads. The tissues play a less passive rôle than such a theory postulates, and tend to develop along certain definite lines, even when deprived of the directing action of the genital hormone. The imprint of sex has been placed on them at a far earlier date than was formerly supposed. Especially would this imprint of sex appear to have been placed on those specialised tissues that become the glands of internal secretion, so that it is not unlikely that other hormones besides those elaborated by the gonads play an important part in the development of the secondary attributes of sex. Exactly what that part is, and what action each member of the endocrine circle exerts on its fellow are, however, questions far beyond the scope of this paper. All that it is necessary for present purposes to remember is that the whole question of the influence of the internal secretion of the testis on the development of the secondary sex characters is far more complicated than was at first sight believed, and that the old view that these characters developed simply as the result of the response of plastic tissues to a stimulus supplied by a sex hormone is inadequate.

Inadequacy of the Hormone Theory in its Simplest Form.

Yet another proof of the inadequacy of the hormone theory, in its original simple form, to account for the development of the secondary sex characters is furnished by the existence of that rare but extremely

FIG. 1. FIG. 2.



Gynandromorphic pheasant.
Left lateral view showing plumage of cock and development of spur. Right lateral view showing plumage of hen bird and absence of spur.
(Illustrations kindly lent by Mr. C. J. Bond.)

interesting condition known to biologists as "lateral gynandromorphism." In this condition the individual develops characters of one sex on the right side of the body and of the other sex on the left. Gynandromorphs, although extremely rare in vertebrates, are not uncommon amongst insects. The best example of a vertebrate gynandromorph that occurs in literature is that of the bullfinch described by Poll. In this bird the male and female plumage were sharply separated on the two sides of the body, the right side of the breast being red, as in the case of the normal male, and the left side grey as in the female. On the right side there was found a testis and on the left an ovary. A somewhat similar case of gynandromorphism occurring in a pheasant has been described by C. J. Bond. In this case an ovitestis was found near the mid-line of the body containing well-marked ovarian and testicular tissue. The left side of the pheasant was male in character as regards plumage, development of the red skin surrounding the eye, the presence of a spur on the leg, and the size of the bones of the tarsus. The right side of the bird was female. Through the courtesy of Mr. Bond I have been enabled to publish a photograph of this interesting bird (see Figs. 1 and 2).

In the face of these curiosities it is necessary to presuppose that there exists a difference in the tissues of the two sides of the body, the testis or the ovary

acting as a stimulus to the development of the sex attributes rather than as a source of differentiation. In other words, in the cases of lateral gynandromorphism cited above, the localisation of sex gland and sex character in different halves of the body has a common genetic cause. They are not causally related the one to the other. As C. J. Bond has pointed out, what is true of these cases is also probably true of normal individuals, so that "in addition to the sex gland with its hormone secretion we must also recognise a somatic or peripherent factor in the causation of secondary sex characters. No amount of hormone will bring about the development of secondary male characters in individuals and in tissues in which the rudiments of such characters are absent. On the other hand, sex gland and somatic rudiments being given in heredity, the due development and the continued growth of the sex character depend on the presence of the sex gland and on the integrity of its internal secretion."

Is the Source of the Internal Secretion of the Testis in the Interstitial Cells?

It has long been known that in the testes of mammals in addition to the cells of the seminiferous tubules there are other elements lying between the tubules and known as the interstitial cells, or sometimes as the cells of Leydig. Within the cytoplasm of these cells may be seen various granules, acidophile, basophile, and pigmented, as well as certain peculiar crystals, the whole giving them the structural appearance of secretory gland cells. It is not, therefore, surprising that the theory should have arisen that these cells are responsible for the internal secretion of the testicle. This conception of the significance of the interstitial cells received such support from the experimental work of Ancel and Bouin published in 1904, that since that time the interstitial tissue of the testis has become known in French literature as the "glande interstitielle du testicule," and in German as the "Pubertätsdrüse."

Ancel and Bouin's arguments in favour of the interstitial cells forming the internal secretion of the testicle were based partly on observations on cases of cryptorchism and partly on animal experiments. They pointed out that in the retained testicle of man and of all other animals, although the seminiferous tubules are ill-formed, the interstitial cells are generally abundant. It is well known that, although a cryptorchid is usually sterile he is sexually fully developed. This association of virility with sterility can easily be explained if it be supposed that the internal secretion is formed in the interstitial cells. Moreover, the fact that in cryptorchism the interstitial cells are if anything increased rather than diminished in number would explain why an animal with a retained testis—e.g., the variety of stallion known in veterinary circles as a "rig"—is usually more excitable and sexually vigorous than an animal with a normally-placed gland.

Ancel and Bouin's experiments consisted in removing the testicle of a rabbit on one side and of ligaturing the vas on the other. On examining the testicle on the ligatured side some six months after the operation these workers found that whereas the tubules had to a very large extent degenerated as the result of the ligature a great increase of interstitial cells had taken place. This increase they regarded as a hypertrophy compensatory to the loss of testicular tissue on the opposite castrated side, and since the external secretory action of the testicle had been put out of action by the ligature, they deduced that it was the hormone-forming tissue of the gland that had hypertrophied. They also observed that in none of the animals used for this work was sexual desire impaired as the result of the operation. Indeed, in some cases ligature of the vas would seem actually to have increased the sexual appetite. As the ligature had brought about a regression of the tubules with a disappearance of all but a few spermatogonæ and Sertoli cells, Ancel and Bouin concluded that the internal secretion of the testicle must of necessity be formed entirely by the interstitial gland.

As a result, to a great extent, of this work the theory that the internal secretion of the testis is formed only in the interstitial cells has been generally accepted. Of recent years, however, various investigators have pointed out that Ancel and Bouin's proofs that the interstitial cells are the source of the internal secretion of the testis are by no means conclusive. Doubts have been expressed concerning the validity of their deductions and observations brought forward within the last few years that make it, in the writer's opinion, very difficult any longer to accept the view that the interstitial cells are entirely responsible for the elaboration of the internal secretion of the testis. Since a great deal of work, and particularly the work of Steinach in Vienna, has been based upon the assumption that the interstitial cells form the hormone if the testicle, it is worth while considering, in greater detail, the arguments that may be brought against this theory.

Arguments Against the View that the Interstitial Cells are Solely Responsible for the Internal Secretion of the Testicle.

Before reviewing the facts that stand in opposition to the theory of Ancel and Bouin, it is to be noted that a hypothesis that locates the formation of an internal secretion in the tubules rather than in the interstitial tissues is in closer conformity with what is already known of internal secretions in general. The seminiferous tubules are ectodermal in origin, and it is from the ectoderm that the glands of internal secretion are generally derived. The interstitial cells, on the other hand, would appear to be mesoblastic structures appearing in the primitive genital trace at a very early phase of embryonal development before the seminal cells have assumed their cytological character (Biedl). It is unusual for structures derived from mesoblastic tissues to assume the work of furnishing an internal secretion. Nor is the fact that the seminiferous tubules have already the work of forming the external excretion, in itself an argument against their being responsible for the elaboration of the internal secretion as well, for we have the well-known precedent of the hepatic cells that are responsible for both the glycogenic and the biliary function of the liver. On a priori grounds, therefore, the view that the internal secretion of the testis, as well as the external, is formed by the cells of the tubules is not unlikely.

For the sake of brevity, the arguments in favour of the internal secretion being formed by the tubules of the testis may be summarised as follows:—

1. Although it is true that there is no spermatogenesis in the tubules of the cryptorchid the germinal cells of the tubules are always present, as well as the interstitial cells. The possibility, therefore, that it is in the former rather than in the latter cells that the internal secretion of the testis is formed can never be altogether excluded. No case has yet been recorded of the development of secondary sex characters in the complete absence of all tubular elements.

2. The commonest type of hermaphrodite found in man is an individual with the secondary sex characters of the female (breasts, hair development, distribution of fat, psychology, &c.) and the primary sex glands of a male. A section of the testicle in such a hermaphrodite always reveals the presence of numerous well-formed interstitial cells which, as in the case of the testicle of the cryptorchid, are generally increased in number. If it be assumed that these cells are the seat of formation of the internal secretion, it is difficult to understand why in the face of this superabundance the secondary male characters of the hermaphrodite should have entirely failed to develop.

3. Although ligature of the vas produces definite changes in the tubules, these changes are generally in the nature of regression rather than of complete destruction. After ligature the spermatoblasts, spermatocytes, and, to a variable extent, the spermatogonia, disappear, but the cells of Sertoli escape, so that the possibility that these elements form the internal secretion can never be excluded. Moreover,

the action of the ligature is not permanent, since if the examination of the testicle be postponed, say, for a year after ligature, a rehabilitation of the tubules will be found to have taken place. That this regeneration of the tubules is not due to any re-establishment of the patency of the vas is proved by the fact that the lumen of the vas, as well as that of the tubules, is found to be distended with fluid. These observations of Steinach on the temporary nature of the results produced by ligature of the vas have since been confirmed by other workers, and notably in experiments on dogs.

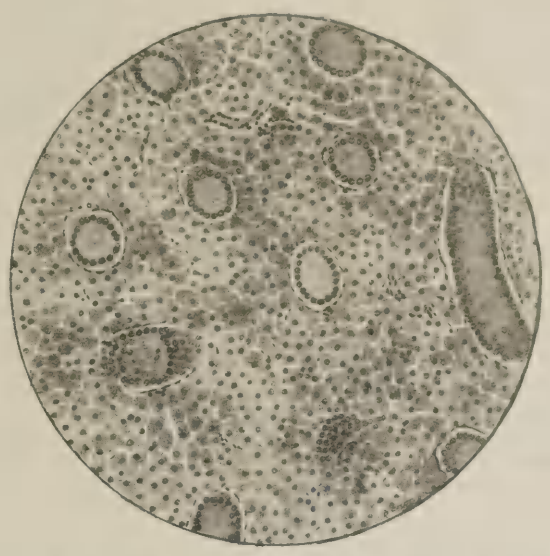
4. Lipschütz has shown by means of partial castration experiments carried out on animals that there is no normal relationship between the number of interstitial cells in the testis and the degree of masculinisation of the animal. Although masculinisation never occurred in the absence of interstitial cells, he found that as little as 1 per cent. of the total tissue of the testes was sufficient to bring this masculinisation about. In the face of this observation it is impossible to agree with Ancel and Bouin that the increase of interstitial cells seen in their ligature and castration experiments was in the nature of a hypertrophy compensatory to the removal of the testis on the opposite side.

5. In many of the lower animals, such as the triton, no cells resembling the interstitial cells of the mammalian testicle can be found. It is difficult to believe that in the higher animals a transference of the endocrine function from the tubules to the interstitial cells could have taken place, since this would mean that a function originally due to epithelium had been handed over to connective tissue.

6. Voronoff and Retterer have shown that when a testicular graft is removed and examined histologically it is found to be composed entirely of cells derived from the tubules. These resemble in appearance the cells found in the tubules of an infantile testicle, and a careful search shows that the interstitial cells have completely disappeared. Nevertheless, these grafts in the case of Voronoff's experiments with castrated goats had been sufficient to bring about the masculinisation of the animal, and were, therefore, it is to be presumed, a source of sex hormone. My own observations, to be described later, confirm this view that the interstitial cells rapidly disappear from testicular transplants, the germinal cells of the tubules alone surviving.

7. In animals whose sexual activities are subject to a seasonal variation, a definite cycle of change may be observed to occur in the histological appearance of the testis. This cycle has been studied by different observers working with different animals, and although discrepancies occur in their interpretation, the balance of opinion would appear to be that the changes seen are not such as to support the view that the interstitial cells are the source of the internal secretion. Champy, in studying the testes of the batrachia, noted the presence of a large number of interstitial cells during the period of rest. These disappeared with the onset of the period of sexual activity. In the dormouse and the camel, who breed only in summer, and in the kangaroo and the stags, both of whom have an equally restricted mating season, he noted the same phenomenon. On the other hand, Stieve, in studying crows, arrived at the conclusion that the interstitial cells undergo no modification either qualitative or quantitative during the seasonal development of the testis, but that the tubules increase considerably in size. Benoit, however, repeating this work on certain tropical birds, maintained that there does actually occur a hypertrophy of the interstitial tissue, but that the hypertrophy is obscured by the great increase in the total volume of the testis that takes place at this time. My own observations on this subject have been made on moles who have a short breeding season during January and February. If a section of the testicle of a mole be examined in autumn, it will be found that the interstitial cells are so abundant that in a rough calculation they must form four-fifths of the total volume of the testis. When suitably stained the cytoplasm is seen to contain numerous granules of lipoid material. The tubules, on the other hand, are in a resting state, and there is a total absence of spermatogenesis (see Fig. 3). At the beginning of December the picture is somewhat similar, but the relative volume of the interstitial cells to the tubules has diminished. In January and February the

FIG. 3.



Section of testis of a mole in September, showing enormous development of the interstitial cells associated with a condition of rest in the tubules. Section stained by Scharlach R. to show the lipoid granules with which the interstitial cells are heavily charged.

tubules have increased enormously in volume and the interstitial tissue has become relatively insignificant.

Whatever may be the significance of this cycle of changes occurring in the testes, it is difficult to find any satisfactory explanation based on the supposition that the interstitial cells are the source of the internal secretion. If Ancel and Bouin's theory is correct, why do the cells responsible for the sex hormone loom so large at a time when the sexual activity of the animal is nil, and how can we explain their gradual diminution as the period of rut draws nigh? Some other explanation of the rôle played by the interstitial tissue must be sought.

The Function of the Interstitial Cells.

If the interstitial cells do not form the internal secretion of the testis, what is their function? The most probable answer to this question is that they are trophic cells, whose part it is to take up nutritive material from the blood and to pass it on to the tubules. Régaud, indeed, has shown that some such substance does in actual fact pass from the interstitial cells to the cells of Sertoli.

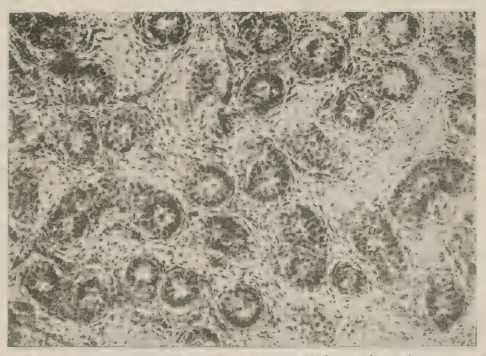
The testes, especially those of animals with a rutting season, are, as we have seen, subject to great changes in their state of activity. From the condition of rest they are plunged into one of intense activity, and in the case of the animal with a limited breeding season this change is associated with a great increase in the size of the tubule. In order to facilitate this sudden change from rest to activity the existence of a store of nutrient material ready at hand is of great importance, and it is in those animals in whom the change from rest to activity is most abrupt that this convenient store of material is actually found, in the form of large masses of interstitial cells heavily laden with lipoid granules. In animals, like man and the dog, who are capable of breeding all the year round, and on whose testicle no sudden demands are made, the warehouse of interstitial cells is comparatively small.

If we turn from comparative anatomy to a study of the development of the human testis from fœtal life until the onset of old age, again we find facts that suggest that the interstitial cells furnish a storehouse of nutritive material for the tubules rather than an internal secretion.

The Interstitial Cells from Birth to Old Age.

A microscopic section of the human testis at or just before birth resembles that of a mole during the resting season, inasmuch as the interstitial tissue appears more abundant than the tubules (Fig. 4). When suitably stained and examined under a high power many of the interstitial cells are seen to be full of a lipochrome substance distributed in the form of granules throughout their cytoplasm. In the seminiferous tubules no differentiation of the cells has at this time taken place. After birth a fairly rapid increase in the seminiferous tubules occurs, so that at four months they would appear to have nearly doubled in size (Mott). During this period of rapid development of the tubules the interstitial cells become less plentiful and the cytoplasm of those that remain appears less heavily charged with granules than was the case at the time of birth (Fig. 5). The testicles maintain this condition until about the time of puberty, when a great increase in the interstitial cells is again noted the increase being followed by a rapid development of the tubules and by the appearance therein of active spermatogenesis. Throughout the years of vigorous sexual life the interstitial cells remain more or less constant, but with the onset of decline there occurs a slow diminution in their size and number. So long as spermatogenesis persists some interstitial cells are usually to be found, but with the cessation of the reproductive function they disappear. As, however, spermatogenesis is sometimes found in the testes of

FIG. 4.



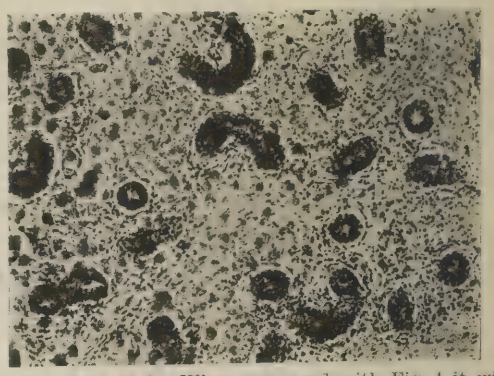
Testis of a twin fœtus showing a condition that is comparable to that seen in the testis of a mole during resting season. Between the tubules are a number of interstitial cells.

very old men the interstitial cells may in actual fact persist to a ripe old age.

The theory that the interstitial cells are trophic explains the single, life-long cycle of the human testis as satisfactorily as it does the annual cycle of the rutting animal. In each case the period of rapid growth of the tubules is preceded by a great accumulation of interstitial cells and lipoid granules. In the human being the periods at which this accumulation occurs is at birth and just before puberty; in the rutting animal it is during the season of rest. In both cases the number of interstitial cells diminish pari passu with the development of the tubules and the appearance of spermatogenesis. Equally satisfactory is the trophic theory in supplying an explanation of the appearance of the testis in cases of cryptorchism. In the cryptorchid the development of the testis has for some reason or other stopped short of spermatogenesis. What the actual cause of this arrest may be is immaterial, the point of importance being that the tubules remain inactive, and that as a consequence of this inactivity nutritive material accumulates in the interstitial tissue. The supply of trophic material here exceeds the demand.

So is it when an arrest of activity in the tubules is artificially produced by such an operation as ligature of the vas. Vasotomy, as Ancel and Bouin showed, is followed by regression in the tubules and an increase of interstitial cells. Their observations are correct but the deductions they draw from these observations are fallacious. The increase in the interstitial tissue is in the nature not of a compensatory hypertrophy but rather of an accumulation from disuse. Although

FIG. 5.



Testis of a child of 3. When compared with Fig. 4 it will be seen that a marked increase in the tubules has occurred at the expense of the interstitial cells, which in this section have entirely disappeared.
(Blocks of Figs. 4 and 5 kindly lent by Sir Frederick Mott.)

the sexual vigour of the animal may, as Ancel and Bouin observed, be augmented by ligature of the vas, this exaltation is not the direct result of the increase of interstitial cells. No direct relationship can be established between sexual activity and richness in interstitial cells. Stieve has, indeed, shown that the stuffed geese of Strasbourg possess more interstitial cells than normal geese, and that nevertheless they are less active sexually than the normal animal. Prominence of interstitial cells usually means accumulation of nutritive material, the surplus being due either to over-feeding or else to under-action of the tubules.

Roughly speaking, in the healthy testicle the prominence of the interstitial cells is inversely proportional to the activity of the tubules. With the onset of old age or in disease this balance is upset, so that a decline in the activity of the tubules is associated with a diminution in the interstitial cells. Complete degeneration of the germ cells is invariably followed by an equally complete degeneration in the interstitial cells.

Conclusions.

The conclusions that may be drawn from the above may be tabulated as follows:—

1. That although the testis, through the medium of its internal secretion, exerts an important influence on the development of the secondary sex characters, its acts as a stimulus to their growth rather than as the source of their origin.

2. That the other organs of internal secretion, such as the pituitary and the suprarenals, exercise a control over the development of the secondary sex characters which is only of less importance than that exercised by the testicle itself.

3. That the influence exerted by the various endocrine glands on the development of the sex characters differs in different animals and in the two sexes.

4. That the internal secretion of the testis is formed not by the interstitial cells but by the cells of the tubules.

5. That the interstitial cells store up nutritive material for the use of the tubules, their function being, therefore, trophic rather than secretory.

It is obvious that these conclusions have an important bearing on the organotherapy of the testis. If the internal secretion of the testis is only one of the factors regulating the development of the secondary sex characters it is obvious that too much must not

be expected of treatment by orchitic extracts or by testicular grafts in those cases of eunuchoidism in which deficiencies in the rest of the endocrine system exist. Moreover, if the interstitial cells do not form the internal secretion of the testis, the observation that they increase in number after the operation of vas ligature cannot be taken as a proof that the output of sex hormone has been correspondingly increased. In other words, if the function of the interstitial cells be trophic rather than secretory, the arguments in favour of Steinach's operation that are based purely on the histology of the testis after ligature fall to the ground.

These practical points will be discussed fully in a later paper dealing with the treatment of testicular insufficiency by means of testicular grafts and by Steinach's method of ligature of the vas.

SCHISTOSOMIASIS IN CHINA:
BIOLOGICAL AND PRACTICAL ASPECTS.[1]

BY ERNEST CAROLL FAUST, M.A., PH.D.

(From the Parasitology Laboratory, Department of Pathology, Peking Union Medical College.)

FOLLOWING the discovery of a Japanese variety of schistosoma, *S. japonicum*, by Katsurada (1904) and Catto (1905), and the description of its ova as found in fæcal examinations, several missionary physicians in China observed in their clinics the presence of similar ova in stools of patients who suffered from Hankow fever, Kiukiang fever, Yangtze valley fever, urticarial fever, or some other locally-named malady. This Japanese form of schistosoma came to be accepted as an entity in China, but it occurred to me, in association with my colleague Dr. Henry Edmund Meleney, that the identity of the Chinese form with the Japanese worm must be established, and its life-history demonstrated, before further progress could be made in attacking the disease. We discovered a Chinese mollusc serving as an intermediate host, and this enabled us to tackle certain practical phases of the problem.

Plan of Investigation.

The course of events in the investigation which we carried out was as follows: (1) The development of the miracidium-sporocyst stage of the Chinese worm was first demonstrated in the Japanese snail. (2) The Chinese intermediate host was discovered in the Soochow area, and the experimental proof established that this was a true intermediate host of the worm, by infecting mice with cercariæ from infected Soochow snails, and infecting uninfected Soochow snails with miracidia hatched from Chinese eggs. (3) The development of the Japanese worm in the Chinese snail was then demonstrated.

The proof of the ability of the Chinese worm to develop in the Japanese snail was made possible through the gift of a large number of uninfected *Blanfordia nosophora*, which Prof. S. O. Yoshida, of Osaka, Japan, sent me in December, 1921. In February, 1922, we had under observation a Chinese patient with schistosome eggs in the stools. The stools of this patient were washed for several days, the miracidia hatched out, and a number of the Japanese snails subjected to infection. Previous to this time we had found that the ordinary molluscs of the Peking area—*Viviparus quadratus*, *Planorbis möllendorfi*, and *Lymnæa plicatula*—could not be infected with this species of miracidium. In the case of specimens of Blanfordia, however, the miracidia became positively attracted to the snail as soon as they came within a few millimetres of it, and proceeded to attack the nearest part of the mollusc. In this way a series of *Blanfordia nosophora* was obtained, infected with miracidia of *Schistosoma japonicum* from Chinese sources. This demonstrated clearly that the Japanese intermediate host of *Schistosoma japonicum* was susceptible to an infection of schistosome miracidia from a Chinese source. This led us to postulate that the molluscan host in infected districts in China must be either the same species of mollusc or a closely related one.

In order, then, to know the condition under which the snail was to be found in China, we studied the bionomics of the Japanese species, its preference for certain types of water, its relation to the various water levels, and the damp soil stratum immediately above the water line, as well as the level of the water at which it was attacked by the miracidia. From our observations we predicated that the snail would be found only near quiet, clear, shallow water; that it would more likely be found on overhanging moist banks at the edge of the water than in the water itself, and that infection by the miracidia would ordinarily occur just beneath the water level. We then chose Soochow, an endemic centre in the lower Yangtze Valley, where conditions were favourable for study, and during the month of August, 1922, Dr. Meleney undertook to discover the intermediate host of *Schistosoma japonicum* for that area. He made the Soochow Hospital his headquarters, and in coöperation with Dr. J. A. Snell, entered upon a search for the mollusc in the region immediately to the north and east of Soochow city, where clinical cases were known to occur. The party left Soochow by motor-boat along the main canal, passed north to the railroad bridge, thence by way of a secondary canal into a region which had frequently sent cases to the hospital. After some search in the rice fields, where only dry shells were found, a man was encountered with marked clinical symptoms of schistosomiasis japonica. Examination of fæcal specimens from persons hailing from a small village in the vicinity revealed eggs of *Schistosoma japonicum*. The village was observed to be on a terminal canal, and examination along the overhanging banks of this waterway just above the water's edge disclosed many specimens of a minute tapering snail, in many respects resembling *Blanfordia nosophora*. The snails were taken back to the hospital laboratory and dissected in the usual manner; 28 per cent. of the snails contained schistosome cercariæ, while one snail contained an oculate fork-tailed cercaria. The former were placed in a museum jar in water, and laboratory mice were submitted to infection. Fourteen days later one of these mice was autopsied, and about 100 immature schistosome worms were obtained from its liver and mesenteric veins. Another mouse was kept until the thirty-first day, when examination at autopsy revealed the presence of many mature male and female schistosome worms morphologically similar to Japanese specimens which we had previously studied. Some of this same collection of snails harbouring cercariæ were later taken to Peking and used to infect mice which had been born in Peking, and had, therefore, never been near an endemic area. Another collection of the same

[1] Abstract from an address recently delivered before the Royal Society of Medicine (Section of Tropical Disease and Parasitology).

species of snails within the city of Soochow, from the bank above the water's edge, was found to contain no infection, so they were submitted to an invasion of schistosome miracidia hatched out from local material. The snails were taken to Peking and kept in moist earth. After about three months they were placed in water, where they discharged large numbers of schistosome cercariæ, which were used to infect dogs. Many other species of snails from the Soochow area were collected and examined, but none contained the schistosome cercariæ. When examined later, none of these subjected to invasion by miracidia hatched from eggs of *Schistosoma japonicum* harboured schistosome larva.

In order to complete our proof of the ability of the miracidia of *S. japonicum* to infect any member of the group of closely related snails, certain of the Soochow schistosome snails that were known to be uninfected were submitted to an infection with miracidia hatched from eggs obtained from the fæces from dogs that had been infected with Japanese material. These were equally infectible; the miracidia readily attacked them. On examination about ten weeks later these snails contained mature and maturing cercariæ. The mollusc harbouring the schistosome cercariæ from the Soochow area has been kindly identified for us by Mr. Bryant Walker, of Detroit, Michigan, who regards it as *Oncomelania* (*Hemibia*) *hupensis*, Gredler.

Life-History of Schistosoma Japonicum.

The purpose of this portion of the study as worked out by us was twofold: (1) To obtain certain biological and morphological data in respect to the worm which were doubtful or obscure; and (2) to determine certain phases of the life-history which might be used as barriers in undertaking control of the infection.

The egg of *Schistosoma japonicum*, when first laid by the female, is a double convex oval disc, with a thorn or abbreviated spine on one side near the anterior end. It is always present in the immature eggs, but is usually much less conspicuous in the mature egg. The mucoid secretions from the lateral glands of the miracidium within the egg-shell ooze out through the shell and serve as an outer sticky cover for the egg. The eggs hatch best in a water medium, where fermentative agents are reduced to a minimum. In pasty stools exosmotic phenomena soon set in and produce the death of the miracidium within the shell. The miracidium dies in a medium above 45° C., but will survive a temperature of 4° C. for months at a time. It will live in freezing temperatures for a brief period (as low as minus 17° C. for an hour or less) provided the medium is water and not fæces. It seems probable, therefore, that the eggs can survive all water conditions which obtain in endemic areas, but soon become non-viable in night-soil dumps which are exposed to the weather.

The miracidium of *Schistosoma japonicum* displays a chemotactic response, not only to the susceptible mollusc when this chemotaxis is once established, but also to the mucus secreted by the mollusc. Experimental data show that all soft parts of the susceptible snail are not only equally liable to attack, but also to penetration. In other words, there is no selective penetration since invasion through the tissues of the head is as common as penetration of the gill filaments. In the former case, as in the latter, the miracidium penetrates the tissues *as a miracidium*, with its full equipment of cilia and secretory glands. Several days elapse before these structures disappear. In the meantime the larva has either secured entry into the lymph spaces of the mollusc or has developed an artificial lymph space around itself: sooner or later it gains access to natural lymph channels. The development of primary and secondary sporocysts, and the development of the fork-tailed cercariæ to maturity require a period of seven to nine weeks. Under natural conditions in the field, seven weeks is probably the period ordinarily employed.

It appears that the mature cercariæ accumulate within the snail until a certain tension of the host tissues develops, when they erupt spontaneously. When infected snails which have been dry for some time are placed in water they discharge their brood within a few hours. If they are taken out of water and placed in dry earth for a period, then later returned to the water, a second discharge usually results, although this is not ordinarily as heavy as the first. Cercariæ of *Schistosoma japonicum* ordinarily swim out of the snail-shell tail first, employing an anchor-fluke movement. Soon after a brood has been discharged they are seen to congregate under the surface-film of the water immediately above the snail, where they become pivotted by the attachment of the ventral sucker to the surface-film. Any object which comes in contact with this surface-film is likely to remove cercariæ from the water. It seems probable, therefore, that the actual first contact of a schistosome cercaria with a suscepible mammal is a fortuitous one, and is not superinduced by a chemotactic stimulus as is that of the miracidium for the susceptible mollusc host.

Invasion of the Mammal through the Skin.

The cercaria attacks the skin with the capillary ends of its cephalic ducts, pouring out through them the proteolytic ferments secreted by the cephalic glands. During this period, if not before, the tail of the organism is dropped, so that the larva enters the mammal not as a cercaria but as an agamodistome. Penetration may be effected in a few hours or may require a longer time. The earliest stage at which we have been able to recover young living worms from experimental animals is 23 hours after infection, when specimens were obtained from the popliteal lymph-node of the rabbit. It usually requires two days or more for them to reach the venous circulation. They pass immediately through the heart to the lungs, where a certain number, particularly in heavy infections, penetrate the tissues of the lungs, producing lesions thereby, and thus reach the pleural cavity. They become side-tracked here, however, and, unable to continue their course, degenerate in a few days. The majority, however, pursue the normal course and pass through the capillaries of the lungs into the arterial circulation. They apparently have an equal distribution throughout the systemic circulation, since at this stage they are recovered from peripheral, renal, and splenic arteries, as well as from the mesenteric system. But only those that get through the mesenteric capillaries into the portal system arrive at a suitable location for growth. The others behave as foreign-body emboli, and are probably the cause of the dermatitis observed early in the infection. The course within the body is, therefore, one definitely involving blood-channels.

Development and Pairing of Adult Worms.

While a certain development takes place during the migration from the skin to the portal system, functioning of the digestive tract takes place only after arrival within the portal vessels. It seems highly probable that the young schistosomes first pass into the intra-hepatic portion of the portal vessels, where they reside until sufficient muscular development has been attained, so that they may crawl back into the mesenteric veins. Here they mate (at about the seventeenth day) and become adult, some as early as the twenty-fifth day. Worms at this time lie in the smaller mesenteric veins and even in the capillaries, where the eggs are laid, and, by pressure, and later by digestive ferments from the miracidium within, break through to the intestinal lumen.

During the migration from the skin to the portal system, but more particularly later within the portal system, the worms respond to a definite growth stimulus. Our first experimental worms were recovered from the liver 70 hours after infection, but migration from the lungs continues through to the seventh day, after which time the worms are too large to pass the capillaries, and, having used up all of their digestive-gland secretions, are unable to migrate of their own accord.

Distribution of Schistosomiasis in China.

Altogether the endemic territory in China is much more extensive than the five known infected districts

in Japan. The latter amount to considerably less than one-tenth the known territory endemic for the disease in China, and are, in reality, minute replicas of the Chinese area, although on the whole they are probably more intensively infected. While foreign sport dogs are commonly found to harbour the disease in endemic areas in China, native dogs are less heavily infected, possibly due to their dislike for water. In China man alone is the important definitive host of the disease.

Diagnosis and Therapy in Schistosomiasis Japonica.

Little careful study has been made in China of the early stages of schistosomiasis. The natives do not seek medical assistance for the infection until it is far advanced, while most early cases which are diagnosed by the presence of eggs in the fæces are usually afflicted with more serious complications.

Houghton (1910) has classified the advanced cases as follows: (*a*) Typical cases, with large liver and spleen, and with fluid in the peritoneal cavity and blood and ova in the stools. (*b*) Cases showing only splenic enlargement, with or without blood or ova in the stools. (*c*) Cases negative except for marked eosinophilia. (I have indicated my doubts about the specificity of a high eosinophil count under such circumstances.) (*d*) Latent cases, showing ova in the fæces, but no bodily reaction.

The earlier treatment of schistosomiasis in China was entirely symptomatic. In Japan quinine and arsenicals were tried without success. In 1913 Hutcheson used emetine on some of his cases in Kashing, and believed that the drug deserved further trial. Following the introduction of tartar emetic treatment for Egyptian bilharziasis by Christopherson in 1917–18 certain hospitals in China undertook to use this drug in their schistosomiasis clinics. In all cases within my knowledge the patients have been taken into the hospital and treated in the wards. Clinicians in China, who have given tartar emetic a trial, agree that "results are uniformly good when patients have stayed in the hospital until pronounced cured, and when complications have been avoided." Tootell (1923), of Changteh, Hunan, reports cures for 50 per cent. of all patients who received treatment, while 29 per cent. more were improved, although they still harboured eggs on leaving the hospital before treatments were completed. In other centres where the treatment has been given a fair trial similar success has been attained. Although Reed (1915) regards emetine as ineffectual, Tyau (1922) favours its use.

Control of the Disease in China.

Prophylactic measures have been undertaken under government supervision to wipe out the molluscs in the endemic areas of Japan. The most successful and practical method yet devised consists in liming the banks along the infected or suspected canals and drainage ditches. In China, the simple but effective measures adopted by the Japanese are still impracticable. In the first case the intermediate host is known as yet only in the immediate vicinity of Soochow, Kashing, and Shaohsing. While the distribution of the disease leads one to believe that the mollusc involved has the same habits of existence in all endemic centres in China, the actual proof yet remains to be demonstrated. In the second place, the whole endemic territory in China is a tremendous one. Neither the disease nor the mollusc is equally distributed over the Yangtze Valley. The infected areas are confined especially to certain districts, such as Soochow, Kiukiang, and Changteh. A practical programme involves a search for the intermediate host in such areas of heavy endemicity, gradually working out from these centres to the districts of lesser infection. It must be remembered, however, that such a programme requires considerable skill on the part of the surveyor, since the mollusc is minute, is easily confused by the layman with immature specimens of the ubiquitous *Melania cancellata*, and is unknown to the natives. On the whole the problem in China seems more likely to be solved on the basis of night soil control. One more fact must be kept in mind in considering such an undertaking so intimately concerning the native farming class—namely, their suspicion that only harm can result from any stranger trespassing on their domain. Coupled with this is the improbability of securing any government coöperation at the present time in China. In spite of these unpleasant facts, the problem of eradicating schistosomiasis from China is ultimately a hopeful one. One must bear in mind that China is an ancient country, that she moves slowly and deliberately, but that she moves surely. The next 50 years will bring much in the way of reorganisation and development in China. It seems not too much to expect that public health and preventive medicine will follow closely upon the steps of improved agriculture and commerce, and that in this scheme of affairs schistosomiasis will not long be allowed to remain an uncontrolled infection in the heart of the country.

Summary.

In working out the problem of schistosomiasis japonica for China, the development of the miracidium-sporocyst stage of the Chinese worm was first demonstrated in the Japanese intermediate host, *Blanfordia nosophora*.

Following this the Chinese intermediate hosts were discovered in the vicinity of Soochow, Kashing, Shaohsing, Fatshan, and experimental proof of their right to this claim was established.

The development of the Japanese worm in the Chinese snail was then demonstrated.

The important factors in hatching of the egg are the maturity of the miracidium and lack of fermentative agents in the medium. The larva withstands cold, but dies at temperatures above 45° C.

The miracidium may enter the tissues of the molluscan intermediate host either by way of the gill filaments or by penetration through the solid tissues of the head or foot.

The cercaria attacks the skin by pouring out proteolytic ferments through the capillary ends of the cephalic ducts, thus digesting and mechanically battering its way through the skin of the definitive host.

Penetration once effected, the young worm utilises the blood channels for its migration through the body to the portal vessels, normally passing through the capillaries of the lungs and thence by way of the left heart into the systemic circulation. While the chances are equal that the worms will pass to all parts of the systemic circulation, only those that pass through the mesenteric capillaries into the mesenteric veins are able to continue growth. Mating has been observed as early as the seventeenth day, and mature eggs have been found in fæces 28 days or later following infection.

The disease, schistosomiasis japonica, has a wide distribution throughout the Yangtze Valley, but is particularly well established in the regions around Soochow, Kiukiang, Tsaoshih, Wuchang, Yochow, and Changteh. It has been located in isolated districts on the central Szechuan plain, in southern Chekiang, at Foochow, above Swatow, and on the North River above Canton.

With a full course of tartar emetic treatment available, about 50 per cent. of the patients suffering from schistosomiasis are cured, while another 29 per cent. are improved. Still others come for treatment too late to secure effective therapeusis. Antimony tartrate is, in most cases, specific for the infection.

While the methods adopted in Japan for eradicating the mollusc host are still impracticable in China except in certain limited areas, it seems reasonable to believe that in the course of a few years measures will be effected to stamp out the infection in China.

THE DEVELOPMENT OF MODERN ANTI-MALARIA CAMPAIGNS.

BY MALCOLM E. MACGREGOR,
WELLCOME FIELD LABORATORY, WISLEY, SURREY.
(Wellcome Bureau of Scientific Research.)

UNTIL an absolutely certain and specific remedy for malaria, in the form either of a protective serum or vaccine or curative drug is discovered, the disease must on the large scale continue to be fought indirectly and somewhat expensively by waging war against its anopheline vectors. Even then, unless the serum, vaccine, or drug were to have the improbable power of inducing a comparatively permanent immunity to malaria, the disease, in its hot-beds, would still have to be combated by campaigns against its vectors. To-day, all over the world, owing to the great increase in wages of even manual labour in the tropics, the expensiveness of this only satisfactory means of fighting malaria is so marked as to cause considerable embarrassment to continued anti-malaria work in many regions. While labour was cheap, obviously it mattered little whether more than the strict essentials of the work were carried out, and we could adopt as our working principle "oil, drain, or fill up all anopheline breeding places in malarious districts"—a simple and satisfactory principle, but one which by recent intensive study of anopheline bionomics we see actually incurs much unnecessary work.

Formerly, working on the old principle, it was sufficient to determine the presence of anopheles locally, and the anti-malaria measures could be safely left in the hands of sanitary engineers and drainage experts. Beyond demonstrating that anopheline larvæ were in the ponds, marshes, streams, &c., and that they no longer existed after the work had been completed, the services of the entomologist were practically uncalled for. Now that the cost of labour has so greatly increased we have discovered that the old principle of developing a sweeping attack against all the anopheline breeding places in a given area, however good the final results may be, is comparable in its extravagance to engaging an enemy on every front, when by a slight study of the tactical position a few master strokes would bring victory without a tenth of the effort or expense.

The new principle to be applied to modern anti-anopheline projects may be defined as "drain or fill up *only* the breeding places in which the *definitely proved* anopheline vector is to be found—disregarding all other waters, no matter how 'typical' they may appear." In following this new principle the full services of skilled entomologists are the foundation and insurance of successful work. In work of this kind, *ipso facto*, the entomologist must rank as general and chief of staff, as it is upon his investigations and plans the success of the campaign depends. Anti-anopheline work is purely entomological work, and modern anti-anopheline work demands the most careful bionomical study of the particular species of the anophelines which are to be dealt with.

Failure of the Mauritius Campaign.

I need only indicate the position and the causes of failure of the anti-malaria campaign in Mauritius, which I have studied recently, to make this point clear. Primarily, owing to insufficient entomological investigations, it had been assumed that only one definite vector of malaria existed in the region. No study of the local specific bionomics of this species had been made, and an extensive and costly anti-anopheline campaign was started with no less an aim than the eradication, as far as possible, of all actual, and what were considered to be potential, breeding-places. No definite plans were evolved other than the oiling, draining, or filling in of what were considered typical noxious waters; the "natural balance" in nature was neither studied nor considered except in so far as assuming that by the importation of large numbers of larvivorous fish the anopheline larvæ would be effectually checked. Moreover, the services of an entomologist had not been utilised for 15 years, the whole of the work being left in the hands of willing but quite out-of-date sanitarians.

After a modern survey of the situation it was found that instead of one anopheline vector three were actually responsible for the intensely malarious condition of the region, and furthermore, that the species formerly regarded as the vector, possibly in certain parts of the island ranked only second in importance. Also it was found that much of the anti-anopheline work which had been accomplished was unnecessary; worse still, by the manner of its execution this work had, in some localities, provided good breeding conditions for what was found to be the other important vector. In addition, it was discovered that waters which had been looked upon as harmless harboured two of the vector species, while another unconsidered type of water harboured the third vector. Naturally all the efforts of the existing anti-malaria organisation had largely failed to produce any amelioration of the malarious condition of the country, and the whole position was to be accounted for simply by the absence of a competent entomologist who could have directed the campaign according to the tactics he found necessary under the local conditions.

Necessity of Dealing Only with Proved Vectors.

Recent study has shown that efficient and economical anti-malaria campaigns can only be attained by the most precise investigation of the bionomics of the local anopheline vectors, so much so that immense dissipation of effort and money is likely to take place unless a full account of the bionomics is available. The old principle of "oil, drain, or fill-in all dangerous waters," in other words, must be relegated to the past as both extravagant and totally unscientific. In an area where malaria is rife obviously the initial investigation should be to determine what species are present, and since the malaria-infectivity of the anophelinæ varies from zero to a high percentage, which species are locally concerned with the transmission of the disease. By modern technique the latter question can now be quite easily determined experimentally, as most of the factors governing mosquito infection and mosquito life in captivity have been ascertained.

It will usually be found that, at most, one or two species in any given region are the important vectors. Hence the necessary anti-anopheline measures are at once narrowed down to dealing only with these proved vectors, and need not involve any attempt at a general slaughter of all anophelines. It then becomes essential to determine the larval and pupal characters of the incriminated anopheles, so that these shall be easily recognised in all their stages of development; and when this is accomplished careful study and registration of all the breeding places must be undertaken. Recognition of the types of breeding places is highly important, but even more important is the registration of the breeding places where the larvæ are actually found.

Underlying the supreme importance of this registration is the common but at present incompletely explained phenomenon that waters with apparently identical geographical and physical characters do not always afford breeding places to the anopheles. Frequently certain waters may harbour innumerable larvæ of the noxious species, while even within a stone's throw of these breeding places, in other seemingly identical waters, no larvæ are ever to be found. Apparently this is due to variations in the pH reaction of these waters, and I have found the use of pH indicators of the greatest value in determining whether any particular water affords normally suitable conditions for anopheline development. It has been found that most of the anophelinæ—probably all except the tree-hole breeders—demand waters with either a neutral or alkaline reaction, and that waters with an acid reaction are unsuitable as breeding grounds. Obviously, therefore, the initial work of the anti-malaria staff is again narrowed down to dealing primarily with the registered breeding places, and not generally with waters of a certain type. Thus the enemy is attacked at once at the positions of its greatest concentration; heavy slaughter follows, markedly reducing with a minimum of effort the numbers of anophelines in the locality. Observation must, of course, be kept upon the apparently identical waters in the vicinity to ensure, with the main breeding places destroyed and with possible changes in the pH index, that the species does not resort to waters from which it has been formerly absent.

In my experience, however, I have found that apparently similar waters which are unsuitable to the species under normal conditions rarely alter. The inimical qualities of these waters, under normal conditions, are usually too great to permit the larvæ to adopt them even when the naturally suitable breeding places no longer exist. Not infrequently I have found in the study of the breeding places of malaria vectors that the types of the breeding places of certain species are so peculiar as to limit the necessary anti-anopheline measures to an astonishing degree, indicating the immense extravagance and futility that widespread oiling, draining, and filling-in operations would involve.

"Natural enemies" in mosquito control are still sympathetically regarded by some people. The idea of utilising a natural force to undertake the necessary labour for us is, I admit, attractive, and not without its element of romance, but I maintain, after attention to this question for many years, that in most anti-malaria campaigns the successful utilisation of "natural enemies" in anti-anopheline work is impossible. Under unnatural (artificial) conditions larvivorous fish are the only "natural enemies" that, in a limited manner, are useful in the destruction of mosquito larvæ. Under natural conditions larvivorous fish have practically no influence in the reduction of the numbers of the larvæ. The fish have to toil for each larva they consume, and Nature's balance provides the larvæ with barriers against the attack by fish—the result being that where one larva is killed, provision is made for the development of another. Consequently, in anti-malaria campaigns, except in artificial mosquito breeding places, such as water tanks, ornamental ponds, drains, &c., fish are useless, and are apt to engender a false faith in palliative measures when direct and ruthless action for the abolition of the breeding places is the only policy of real value.

Propaganda and Instruction.

In all parts of the world to-day, by the conspicuous racial and individual development of peoples, anti-malaria measures which in the past would have been accepted in dumb faith are now frequently brought sharply under public criticism, for good or ill, according to the degree of public enlightenments Careful propaganda and instruction to communitie. by those in charge of modern anti-malaria campaigns is, therefore, of the utmost importance, and the foundations of success are to be laid by preliminary discussion of the objects with the leaders of the communities, followed by concurrent instruction of the people as each of the details of the campaign is undertaken. Each individual who understands the aims thus becomes a nominal member of the anti-malaria staff, and can be made to render invaluable service and relief to the efforts as a whole, instead of developing a policy of obstruction by regarding himself as subject to irritating and needless obligations.

Since it may be said that the foundation of economic and modern anti-malaria campaigns lies in the adoption of direct and permanent measures against only the proved breeding places of the definitely incriminated vectors, and the avoidance of all measures that are merely palliative or which aim at dealing in any locality with the anophelinæ in general, it follows that the command of such campaigns must, in future, rest with the chief entomologist and his staff; these experts will progressively regulate the attack against the vectors in accordance with the measures that are proved necessary, so minimising the expense and length of the campaign, and evading valueless or unnecessary effort.

Medical Societies.

MANCHESTER PATHOLOGICAL SOCIETY.

A MEETING of this Society was held on Dec. 12th, 1923, Dr. E. B. LEECH in the chair.

Dr. J. H. DIBLE opened a discussion on

Pneumococcal Infections,

and was followed by Dr. G. J. LANGLEY. These papers appear in the original columns of THE LANCET this week.

Mr. E. E. HUGHES, speaking of surgical infections, said that pneumococcal peritonitis was a disease of two varieties. The secondary variety affected persons of all ages and sexes, and was a sequence to some active pneumococcal infection in another organ. The primary variety was a disease of girls of about the ages of 2 and 11. This period corresponded to one of active development of the vagina, whilst the vaginal secretion had not yet developed its characteristic acid reaction, and suggested a vaginal infection as the route of entrance of the pneumococcus. The work of McCartney and Frazer had shown that this was the case. In pneumococcal peritonitis the lesions commenced in the pelvis, and the same type of pneumococcus had repeatedly been isolated from the vagina, peritoneum, and blood. Experimental work on rabbits and monkeys had confirmed this route of infection, whereas experimental blood infection was followed by septicæmia without peritonitis. The suggestion was that children at this age—and the disease occurred mainly in the poorer classes—became infected by sitting about upon doorsteps and pavements, and contracting direct infection of the vulva.

Prof. SHAW DUNN said that the conception of involvement of the lung, by spread outwards from the hilum, explained a number of points which had previously been obscure. He looked upon pneumonia very much as a cellulitis of the lung. It was difficult to understand why in some cases the same infecting

agent produced broncho-pneumonia and in others lobar pneumonia, and he was familiar with certain cases in which on post-mortem examination it was difficult to decide whether the condition was really to be designated lobar or broncho-pneumonia—a sharp line of division did not exist. He believed that the reason for such diversity of lesions was possibly a matter of magnitude of the infection: a single large dose might produce a lobar lesion, and a smaller one give rise to broncho-pneumonia.

Dr. A. H. HOLMES urged some objections against the idea of localisation of the early changes to the hilum. He thought that clinically the lesions were not found in that position in the early stages, and, further, that pleural friction was constantly an early sign and this would militate against such a localisation. He thought the disease might begin in the superficial part of the lung, and asked if cases were not met with at post-mortem where there was involvement of the outer portion of the lung and freedom of the root. He wondered if certain of the cases of peritoneal infection which were described as pneumococcal might not be in reality enterococcal infections.

Prof. MATTHEW STEWART said that he thought that the vaginal route of infection was an important one in streptococcal as well as in pneumococcal peritonitis, and quoted a case published by Adami bearing upon this point. With regard to the spread of the morbid process in the lung, he was familiar with cases of lobar pneumonia in which the whole lobe was consolidated except for its extreme edges, which might only show œdema and congestion, but not with the converse condition.

Dr. DIBLE, replying, said that he had never seen pneumonic consolidation of the lobar disease involving the periphery and sparing the centre. He doubted very much if auscultation and percussion would reveal deep-seated early changes in the lung root, and he thought that it was this localisation which was responsible for those cases of "central pneumonia" in which physical signs only appeared late. Early pleural friction was not a bar to the acceptance of the centrifugal spread of the disease as the distance of the pleura from the hilum was only a short one in the root region. He thought that the discussion had shown that the hæmatogenous theory of invasion had now been overthrown in two of the chief pneumonic infections. Bacteriologists realised, probably more acutely than others, from experimental experience, that the blood could usually look after itself in regard to most bacterial infections, and he believed that in the other chief pneumococcal infection—meningitis—the route of invasion was by the Eustachian tube or cribriform plate, and that here, too, the hæmatogenous theory would be shown to be incorrect. In considering the production of broncho-pneumonia he thought that Prof. Shaw Dunn's remarks had left little to be said save that bacterial virulence must also be taken into account, but this was a matter which at the present time was very difficult to assay.

Dr. LEECH thanked the speakers and concluded the discussion.

LIVERPOOL MEDICAL INSTITUTION.

A MEETING was held on Dec. 20th last, Prof. J. HILL ABRAM, the President, being in the chair.

Mr. JOHN T. MORRISON read a note on the

Treatment of Tuberculous Sinuses.

He pointed out the necessity for an efficient and at the same time labour-saving method in a condition of such chronicity and seriousness. He took for granted attention to general treatment along the most approved lines, and went on to speak of the operative treatment—radical operation in a minority of cases, in others removal of sequestra, scraping out a caseous gland, counter incision, and so on. In most, however, patient attention to daily dressing is all that is indicated. For this purpose he believed bipp carefully used to be most suitable. The technique involved strict asepsis. After passing a fine rubber tube to the limits of a carefully explored track, he aspirated pus and then washed out with spirit. Bipp suitably diluted with liquid paraffin was then injected so as to fill the track from the bottom up. The bipp should never be stiff enough to dam back discharge or so thin as to run out of a dependent opening. A dry dressing carefully secured in place may be left a week, ten days, or longer, and should not be touched until an indication arises. The need for re-dressing is enormously diminished and patients so treated, provided the whole of the diseased track is reached, do well, some healing rapidly. The treatment should not be used where active inflammatory trouble is present and only with caution in abdominal sinuses. Chest sinuses are suitable, however, even those with bronchial fistulæ. Cavities in the chest up to half an ounce capacity may be filled with bipp; the larger ones should merely have their walls coated with bipp sprayed on in ethereal solution. The bipp method of treating tuberculous sinuses was a useful addition to one's armamentarium under all circumstances, but when the surgeon was single-handed and skilled assistance inadequate it was invaluable to him.

Dr. NORMAN CAPON read a short paper on six cases of so-called

Hæmorrhagic Disease of the New-born.

He pointed out that examples of hæmophilia and of hæmorrhage secondary to conditions such as sepsis, syphilis, or enteritis should not be included in this category. After a brief description of his own cases, Dr. Capon drew attention to the various theories which have been advanced to explain the abnormalities of coagulation which appear to form the basis of the disease. It was probable that cases might be divided into two groups: one in which coagulation time is lengthened, with deficiency of prothrombin; the other with prolongation of bleeding-time, ascribed by various workers to deficiency of prothrombin, of blood-platelets, or of thrombokinase. The important clinical features were recorded and emphasis was laid on the efficacy of whole-blood administration. This remedy might be given by subcutaneous injection, or, in more severe cases, by intravenous transfusion, using either a superficial vein or the superior longitudinal sinus. The mother is generally selected as donor, and preliminary blood-grouping is then not necessary. Of Dr. Capon's cases five recovered and one died.

Dr. H. H. L. PATCH read a paper on

Dangers During the Administration of Anæsthetics.

Depression or failure of respiration and circulation due to the action of ether and chloroform in the various anæsthetic stages were discussed in detail, special mention being made of overdosage. The dangers of light chloroform anæsthesia were touched upon, with instances of too early a commencement of the operation causing reflex circulatory and respiratory failure. Commentary was made on the mental hyper-excitability produced by the hypodermic injection of atropine prior to the operation. It was held that the sphygmomanometer should be used in all serious cases, and that the accuracy in gauging the fall of blood pressure is a very important point both to the anæsthetist and to the surgeon. The usefulness of Hewett's airway was mentioned and the opinion expressed that with its use bronchitis is not found to follow an anæsthetic more frequently than without it. Dr. Patch held that bronchitis was due to irregular administration or previous disease. The latter part of his paper was devoted to difficulties and dangers found in anæsthetising patients suffering from fear and apprehension, from adenoids, in which condition he advocated ether, and from abdominal conditions. Conditions of spasm of the glottis and overdosage were considered, and finally the possibilities of diagnosing status lymphaticus before anæsthesia were discussed.

Dr. G. F. R. SMITH believed that the advantages of using a pre-operative dose of morphine out-balanced the disadvantages, and emphasised the danger of moving a patient suddenly.

Reviews and Notices of Books.

ANGINA PECTORIS.

By Sir JAMES MACKENZIE. Oxford Medical Publications. London: Henry Frowde and Hodder and Stoughton. 1923. Pp. 253. 30s.

Sir James Mackenzie gives here a most readable account of angina, illustrated by a wealth of clinical material, and at the same time illustrates certain methods of investigation which he considers essential to the practice of medicine. The two most interesting sections are the preface and the tenth chapter, for in these he deals in a broad way with the whole question of health and disease. In a valuable appendix the records of 160 cases are given, including reports of a number of autopsies (22). Sir James Mackenzie differs from some in refusing to consider angina as a disease with a fixed and definite pathology. It is to him a symptom indicating exhaustion of the myocardium, and he correlates the pain of angina with that of renal colic, pointing out that the process by which the symptoms of renal colic are produced is comparable to that provoking angina pectoris. He has here applied his theory of disturbed reflexes in the production of symptoms to the special symptom-complex of angina pectoris. The classification of primary and secondary angina is accepted. In the former he includes those patients in whom changes of a permanent nature are present in the heart. In the secondary the chief deviation from the normal is an undue susceptibility of the nervous system, the result of some influence other than the heart. This classification obviously carries with it certain clear indications as to treatment and prognosis in any particular patient, and the chapter on treatment is a careful exposition of the author's views. While much can be done by skilful management of the patient, he emphasises the fact that in the primary anginas it is wise to recognise that the organic changes in the heart are permanent—as permanent as grey hair and the arcus senilis—and that treatment must be such as to prevent exhaustion of the enfeebled muscle. It is generally accepted that, though there is no constant pathological condition found in the hearts of those dying from angina, nevertheless some degree of coronary disease is a common finding. The significance of coronary disease is, that narrowing of the coronary artery results in a lessened blood-supply to the myocardium, and in the opinion of the author the pain of angina is associated with muscular contraction, as in the case of renal and other colic; and he considers that muscular contraction is a stimulus adequate to cause anginal pain when there is a deficient blood-supply to the heart muscle. Sir James Mackenzie also discusses the origin of anginal pain in those patients in whom no disease of the coronaries is present.

We have in this book a valuable contribution to the study of heart failure—the result of many years of investigation of cardiac failure and of the mechanism of pain.

GRAFTS FROM MONKEY TO MAN.

Quarante-trois greffes du singe à l'homme. By SERGE VORONOFF. Paris: Librairie Octave Doin. 1924. Pp. 251. Fr. 20.

IN this new book Dr. Serge Voronoff has given the results of further work on the subject of testicular grafts. The book contains some of the matter previously published in "Greffes Testiculaires" (1923), as well as entirely new material. Dr. Voronoff starts with a summary of the events that led to his adoption of testicular grafts as a treatment for testicular insufficiency, premature senility, neurasthenia, and debility. He describes how, in 1920, in an attempt to avoid the absorption that inevitably follows the placing of a graft from one of the lower animals in the human body, he employed a testicle derived from an anthropoid ape. For this method of using grafts from an allied species he has coined a new term referring to such grafts as homeografts, to distinguish them from autografts (grafts from the same subject), homografts (from the same species), and heterografts (from entirely different species). As a result of his animal experiments on the subject Voronoff has found that fragments of tissue taken from an allied species survive for a far longer period than a heterograft taken from a widely different species. In other words, a graft from a goat when implanted in a sheep survives for a longer period than a similar graft taken from a dog. The anthropoids being the most nearly allied to man, Voronoff considers them the ideal source of grafts for the human subject.

In one of his human cases Voronoff was enabled to examine a graft that had been taken from an ape some 15 months previously. The examination showed that not only had the epithelium of the seminiferous tubes survived, but that actual proliferation had occurred, so that in many places the lumen of the tubule had been obliterated. Of still greater interest is a similar observation made in the case of a goat that had been grafted with the testicles of a young animal that had not yet reached puberty. When the grafts were removed at the end of 14 months it was found that the epithelium of the graft had actually evoluted during the interval, so that the heads of spermatozoa could be made out, all signs of spermatogenesis having previously been absent. On these observations Voronoff rests his claims that homo- and homeografts not only survive, but may even develop after transplantation. His clinical results at any rate appear to show that the benefit of grafting may be maintained for a period of three and a half years. In one of his cases, however, the effect of the graft would seem to have waned towards the end of the third year, and at the request of the patient—a man of 65—the operation was repeated with results equally happy to those achieved on the first occasion.

The technique used by Voronoff is simple, and is described in great detail in the work under review. The cavity of the tunica vaginalis is always chosen where possible. Should there be insufficient room within the cavity for all the grafts, some of them are attached to the outer surface of the tunica vaginalis, and in order to encourage vascularisation the area of implantation is lightly scarified. The grafts are always placed so that the glandular surface is opposed to the tunica vaginalis, and care is taken that no two grafts come into contact with each other. Following the description of the operative technique are the records of 43 human cases subjected to grafting. In all cases monkeys or baboons were used as donors, only those monkeys being selected which gave clear evidence of having attained the age of puberty, since in certain cases in which younger animals had been employed no results were obtained. Amongst the later articles in the book are papers by the author in collaboration with Dr. E. Retterer on Heterografts and on the correlation between the physiological phenomena and the structure of testicular grafts. These papers are of particular interest and lend support to the view that is rapidly gaining ground that the interstitial cells are not responsible for the elaboration of the sex hormone. As an entirely new application of the principle of grafting, Voronoff has studied the influence of grafts on the healing of wounds. Carrel in 1912 published in New York a note on the artificial acceleration of the growth of connective tissue cultivated in vitro, and showed that the growth of the tissue of a chicken that had been cultivated in vitro could be stimulated by adding extract of embryo to the culture-medium. This suggested to Voronoff that the healing of wounds might also be stimulated by the use of emulsions of various glands such as thyroid, suprarenal, pancreas, and testicle. By bringing fragments of different tissue into contact with the wound he showed that whereas pancreas undoubtedly inhibited healing, thyroid and testicle hastened it. This accelerating action exerted by testicular tissue on a healing wound is evidently not due to any general stimulation of the body, but

to an action that is entirely local. The precise nature of this local action is still unknown.

It is difficult to pass judgment at the present time on Voronoff's new contribution to the subject of testicular grafts. Time and the results obtained by other researchers on this subject will show how far we can accept the views which he puts forward. The subject is one on which the attention of the medical profession has become focused, and others are working along the same lines. However, it may at once be admitted that Voronoff and Retterer have made valuable contributions to the subject in their study of the histology of grafts removed some months subsequent to their vascularisation. That mental suggestion plays a part in the benefits obtained from grafting is certain, but that this can entirely explain the results is extremely unlikely. The book should be read with interest by all.

The Medical Treatment of Disease.

Notes for Students and Young Practitioners of Medicine. Second edition. By Robert Dawson Rudolf, C.B.E., M.D. Edin., F.R.C.P., Professor of Therapeutics in the University of Toronto; Clinician, Toronto General Hospital; Consulting Physician, Victoria Hospital for Sick Children, Toronto. University of Toronto Press. 1923. Pp. 486. $4.

This is one of the most useful books dealing with treatment that have appeared during recent years. The reader who expects to find ready-made prescriptions for every condition will be disappointed, and here we feel that Prof. Rudolf has shown commendable discretion, for it is precisely those lists of prescriptions that form the danger of the majority of such text-books; they lead to carelessness and empiricism. In the present work the reader will find existing therapeutic methods and remedies briefly described, and usually with that critical outlook which marks the scientific observer. Such procedures as the production of artificial pneumothorax and duodenal alimentation are written of in sufficient detail to allow the practitioner to employ them without reference to larger text-books. We are interested to note that the author is lukewarm in his opinion of the surgical treatment of Graves's disease, and that he considers serum therapy of little use in the treatment of chronic bacillary dysentery. Several misprints, such as "construction" for "constriction" on p. 280, require correction, but are not sufficiently numerous seriously to affect the pleasure with which this book will be read.

Oral Hygiene.

By J. Sim Wallace, D.Sc., M.D., L.D.S., Lecturer on Preventive Dentistry, King's College Hospital. London: Baillière, Tindall and Cox. 1923. Pp. 76. 5s.

The teachings of Dr. Sim Wallace on the ætiology and prevention of dental caries are by now a familiar story and have become incorporated to a considerable extent in the current conceptions of dental disease, often without sufficient acknowledgment to their author. It is a disadvantage that there is no authoritative account of Sim Wallace's work within the pages of one book. At present his views are scattered through a series of volumes, with much overlapping and repetition, so that it is by no means easy to gather a comprehensive idea of the various aspects of his investigations. The present volume consists of three papers which have appeared elsewhere, reprinted apparently without alteration. The book is in no sense a text-book on oral hygiene as the title might suggest, though it contains much instructive matter on the subject. The papers have little continuity though they are concerned with the ætiology and prevention of dental caries. To those who have hitherto learned Sim Wallace's views at second hand we commend this book. If they will read the first and third chapters they will find there the essence of his teaching explained in admirably clear language. We do not think the short note on vitamins and hypoplasia can be regarded as a fair commentary on the vitamins and their relation to calcification. The chapter on the progress of preventive dentistry is an interesting historical review, but it is damaged by personalities out of place in a scientific book.

Handbook of Surgery.

By G. L. Chiene, M.B., C.M., F.R.C.S. Edin., Surgeon, Edinburgh Royal Infirmary. Edinburgh: E. and S. Livingstone. 1923. Pp. 592. 12s. 6d.

In his preface the author says that "this small handbook has been written with the object of providing a book for those who have not time to study the larger text-books." Many would hold the opinion that such students or practitioners are not worth catering for. The volume under review could certainly not be recommended as the sole text-book on surgery which the student should read. It is not possible in a book of this size to deal adequately with pathology, or to emphasise the principles upon which surgical treatment is based. Nevertheless, the teaching found in it is sound, as far as it goes, and, as a revision book, the student who has read the ordinary text-book may find it useful.

Ambulatory Treatment of Fractures and Diseased Joints.

By Carel A. Hoefftcke. With an Introduction by Frank Romer, M.R.C.S., L.R.C.P., and Articles by Many Eminent Surgeons and Physicians. London: William Heinemann (Medical Books), Ltd. 1923. Pp. 274. 17s. 6d.

This treatise is written to show the utility of the author's ambulatory extension splints, which have been applied for some 20 years in this country for diseases of the joints and fractures; and the value of the apparatus is proved by the fact that in medical literature, both in treatises and in journals, the merits of these splints have been recognised freely. Further, although Mr. Hoefftcke does not write as a medical man but as a skilled adjuvant to medicine, his treatise is prefaced by introductory communications from medical practitioners, styled eminent in the title, many of whom are justly well known. Mr. Frank Romer, in an introduction, states clearly that he has "recently had the opportunity of seeing patients with diseased joints who have been enabled to lead an active life using the affected joint freely by means of this (Hoefftcke splint) ingenious contrivance." And in our own columns Sir Arbuthnot Lane has written: "The advantages afforded by the forcible separation of the diseased articular surfaces from one another, combined with free movement, are best shown by the use of a really efficient extension apparatus for the leg which does not interfere with the functioning of the diseased joint"—the reference being to the same apparatus.

The principles involved in the construction of various forms of ambulatory apparatus devised by the author, as well as the methods of their application, are fully set out and clearly illustrated in the early chapters of the book, while an historical survey explains the steps by which valuable, and for the most part new, types of splint were arrived at. The main objects aimed at have been to take the weight of the body off the affected limb and produce extension between the articular surfaces in joint disease, while in fractures the intention is to keep the fragments in apposition and to prevent shortening of the limb. Mr. Hoefftcke produces manifold and mutually confirming examples of cases where these objects have been achieved without confining the patient to bed; and the general well-being which is produced by such patients being able to enjoy a natural environment cannot be exaggerated. It is not only that the more free circulation of blood to the site of injury promotes

local improvement, and this rapidly in many cases, but the system of the patient is more adequately strung up so that any improvements secured get full chance of development. In the book will be found numerous ingenious contrivances, fully figured and fully explained, which will assist the medical man to treat patients for numerous conditions from a patella wrench to a diseased hip-joint; while far the greater part of the contents consists of reprints from medical journals or of communications to the author written by practitioners and patients who have had good reason to be pleased with the application of his splints, or with the use of an ingenious extension table to be employed in the manipulation of diseased joints under anæsthesia. The majority of these tributes—which are, by the way, not systematically arranged—include photographs and radiograms of patients before and after treatment, thus conveying different messages of encouragement.

The book is very well written, but in future issues it might be well for the author to note that he has quoted the same words from a well-known surgeon on pages xi. and 84 and 129. All the tributes from the medical profession are not of equal value, but it would be captious to blame Mr. Hoefftcke for recording evidences of professional support which he has received. For throughout the book he writes as a skilled craftsman, leaving the medical profession to record their views of certain of his results. And it should be stated clearly that he works only with the medical profession, and not as one who offers a substitute for medical services.

PHARMACOLOGY AND THERAPEUTICS.

Handbook of Pharmacology, including Materia Medica. By BIRENDRA NATH GHOSH, F.R.F.P.S. Glasg., Examiner in Pharmacology, University of Calcutta. Calcutta: Hilton and Co. 1923. Pp. 396.

OUR text-books on pharmacology have improved in recent years, showing themselves, on the one hand, to be books of applied physiology, and on the other to be the parents of books on treatment. In fact, they have become more rational in their methods, and one result of this change is that it has become increasingly difficult to find a place in them for mere lists and types of preparations and for doses. These the student must know, even though they have to be learnt by heart. However much the examiner is pleased to find that a student has an intelligent idea of the action of mercury, he still rejects him if he gives a poisonous dose of the perchloride or if he cannot prescribe it in a practical manner. The books of writers like Poulsson and A. J. Clark, which centre round drug actions, are a great improvement on the older pharmacologies where the drug and not the action is paramount, but such books are not sufficient for the student. He wants something in addition. B. N. Ghosh's "Pharmacology," which seems really to be an abbreviated form of R. Ghosh's "Materia Medica and Therapeutics," affords the bare facts and lists which it is difficult to pick out in the other books named, a difficulty all the greater now it is customary to give preparations of the U.S.P. as well as of the B.P. This book cannot stand alone, as it does not make the student think, but it is useful as it supplies in assimilable form the concentrated facts which have to be learnt before a man can practise successfully or even safely.

Indian Therapeutics. By D. V. SANDU. Bombay: V. K. Sandu. 1923. Pp. 90 and Supplement.

SCHOOLS of treatment are out of fashion. None has shown itself to be absolutely right; few do not contain some glimmering of truth; all get left behind in the light of scientific research. But the Ayurved or Aryan medical science survives long, and this booklet, by one of the Sandu brothers, who have works for the manufacture of the drugs of this system, lays before English readers the history and merits of the system. The explanatory introduction is of interest, but to the uninitiated the list of drugs with long Indian names and of diseases treated is reminiscent of the herbalist or the quack. "The action of medicines mostly depends upon the belief of the patient in the prescriber and the medicine prescribed. Atmost (*sic*) care should therefore be taken to create confidence and hope in him." These are sentences which show candour, and their sentiment is one in which many English physicians will agree. But in all the material of Indian galenicals there must be something of value, and it remains for pharmacologists and perhaps for the Ayurvedic system to bring it to light. Interest is added to the book by the recent Madras report on native Indian schools, in which the Ayurved school is thoroughly considered.[1]

ECHOES.

By Sir DONALD MACALISTER, K.C.B. Glasgow: Maclehose, Jackson and Co. 1923. Pp. 212. 7*s.* 6*d.*

THIS volume is a reissue of the translations from and into various languages, which from time to time and in different places have appeared from Sir Donald MacAlister's pen. There can be few scholars with such a range of tongues, and not one alive whose learning and literary skill would enable him to translate not only Spanish, Italian, and Russian into English, and Greek and German into Russian, but Provence into Scots, Oliver Wendell Holmes and Robert Louis Stevenson into German, and quatrains of Omar Khayyám and songs of Walter Scott and Calverley into Welsh Rómani. Further, there are translations which are renderings, but not echoes; but Sir Donald MacAlister has well named this collection, for in those cases where the reviewer can apply any personal knowledge—a lamentably meagre range in proportion to the opportunity offered—both the spirit and the lilt of the original have been maintained. Let anyone, without knowing a word of gypsy language, read aloud the chorus of Kipling's "Smuggler's Song" in English, and then the version in Welsh Rómani, and appreciate Sir Donald MacAlister's skill and literary sympathy. He will also be sadly envious of the opportunities for enjoyment which learning has given to the President of the General Medical Council, whose serious business in life the New Year's list of honours celebrates this week.

HYGIENE OF THE VOICE.

By IRVING WILSON VOORHEES, M.S. Princetown, M.D. Columbia. New York: Macmillan Company. 1923. Pp. 212. 12*s.*

THIS little book is divided into two parts, the first intended for the general reader, teacher, or pupil, and written in non-technical language, and the second part intended for physicians or those possessing medical knowledge; but this latter part is not very technical, and is apparently intended for laymen with some medical knowledge quite as much as for physicians. The book is brightly and even humorously written, but is not quite dogmatic enough for the practical pupil; it advises him not to work the voice when he has a cold, but gives no decided opinion on such unsettled questions as the age at which teaching should begin or the use of the vocal registers. The author rightly advocates with enthusiasm a more cordial understanding between teachers of singing and laryngologists. The best chapter is that in the second part on the "tonsil question"; he sent out a questionnaire to 500 physicians and 500 teachers, and concludes that impairment of the voice after tonsillectomy is possible, but very rare; while most cases show an increased range of tone, he decides that abnormally large or diseased tonsils should be completely removed by dissection.

The author pays a high tribute to the work of Sir Morell Mackenzie.

---

[1] THE LANCET, Sept. 29th, 659, 669.

The Conduct of Medical Practice.

A Series of Articles by Experts dealing with the Difficulties Encountered in Professional Life and How to Meet Them.

I.—ASSESSMENT FOR INCOME-TAX: ACCOUNT-KEEPING.

BY W. R. FAIRBROTHER, F.S.S.,
ACCOUNTANT AND INCOME-TAX SPECIALIST.

There was no reckoning made with them of the money which was delivered into their hand; for they dealt faithfully.—II. Kings xxii. 7.

THE completion of his annual taxation return is not a task the average medical man enters upon with gusto; rather does he feel that the ordeal, although not enjoyable, is yet inevitable. Doctors are not much given to a fondness for strict account-keeping, and in all too many cases the Income-tax return, whilst reflecting the receipts fairly accurately, does not as accurately allow for the expenses. The result, of course, is that a needless addition is made to the already heavy burden of taxation which must be borne. Moreover, apart from taxation, it is surely necessary that any professional man should know, at the end of the year, what his net profit amounts to. Not only does this enable him to gauge his financial position, but it affords the evidence of value of the practice required in the event of sale, death, or change of partners.

Having diagnosed the complaint it becomes necessary to prescribe the remedy, which is of a three-fold character—viz., a proper but simple form of account-keeping, the correct manner of computing the Income-tax assessment, and an explanation of the deductions, allowances, and reliefs which may be claimed.

The accounts may conveniently be divided into the correct recording of receipts and payments.

Receipts.—A Call-book or Diary will be kept giving sufficient details in the case of credit cases for a statement to be prepared later. This book would be in the form shown in Table I. It will be observed that one Cash column provides for cash paid at the time and the other for credit bookings. The Credit column must be posted in detail to a ledger, while the Cash

	Analysis columns added through to totals at end of year ..					£	18 19 6	11 9	40	5	1 2 6
1924.										
Jan. 1	To Balances	b/d.	2 9	290 15 10						

column is totalled and entered daily on the receipt side of the cash book. No payments for *past* services are to be shown in the call-book, but such payments are entered at once on the receipt side of the cash book and posted to the appropriate ledger account. The cash book is as shown in Table II.

The receipt side of the cash book should have two cash columns, one headed Cash and the other Bank. Care should be taken that receipts are banked in full and cheques drawn for cash required for payments. When money is banked the Cash column should show clearly the details of the amount, which amount is entered in the Bank column. The Cash column will contain daily totals from the Call-book Cash column, amounts received from credit patients, local authorities, hospitals, Insurance Commissioners, &c. An analysis cash book is advocated in which columns are provided for the extension of the amounts received under the various heads given above, so that a yearly total can be obtained of the receipts from the different sources. Where the banking account is used for private as well as business purposes, dividends, rents, or other private receipts should be entered in the cash book (either in detail or without detail if it is desired not to disclose the detail in the business books) in order that the cash book can be balanced with the pass book. The Analysis columns on both sides of the cash book should be totalled continuously to the end of the year in order to give the figures for the final account.

Payments.—Cheque payments must be distinguished from cash payments by being entered in the Bank column side of the cash book, while cash payments are entered in the Cash column only. Cheques drawn for cash are entered in the Bank column on the payment side and in the Cash column on the receipt side. Both cheque and cash payments will be extended in the Analysis columns. Private payments or cheques to self for private purposes should be extended under the head of "Drawings." Care should be taken to distinguish between capital and expenditure payments. Additions to the previous stock of instruments should be distinguished from replacements, and additions to the consulting-room or surgery furniture from repairs and renewals. Sufficient detail of the payment should be entered—e.g., on entering a payment for gas the quarter year it relates to should be given. Petty expenses, such as postage and fares, may conveniently be dealt with by way of a petty cash book, the cash book being credited and the petty cash book debited with the round amounts allowed for petty cash.

The following is the procedure in case of a cheque being returned by the bank, and later repaid into the bank. On being returned by the bank, it should be entered as a payment in the Bank column and on

C = Carriage. F.A.C. = First Aid Cabinet. † A column headed "Printing, Stationery, &c.," could be inserted next to "Personal Drawings."

being paid in again it should be entered on the receipt side of the cash book in the Bank column. It may be starred on both sides, as shown, to indicate that it need not be posted to the ledger. Cheque books and interest charged by the bank direct through the pass book should be entered in the Bank column on the payment side.

Final Accounts.—With a view to agreeing the final accounts for the year it is desirable that all casts and cross casts throughout the year should be checked from time to time. In preparing a total receipts and payments account for the year all additions to instruments, fixtures, &c., and all drawings must be excluded on the payment side, while on the receipt side private monies must also be excluded. The figures should also be agreed in total and for this purpose the starting bank and cash balances must be added to the receipts and the closing bank and cash balances to the payments. In order that a proper amount may be allowed for depreciation, it is desirable to have an inventory of the business fixtures, fittings, and instruments. The fire insurance inventory will often be a useful guide.

Audit.—Whether it is decided to have an audit or not it is well to have the receipts or vouchers in good order. This is easily effected by numbering the payments in the cash book consecutively. When the receipts come in they should be attached to the statement and numbered with a large number corresponding to the number in the cash book. It will be appreciated that No. 312 may come in before No. 305, but if every receipt is numbered clearly they can later be readily sorted into numerical order.

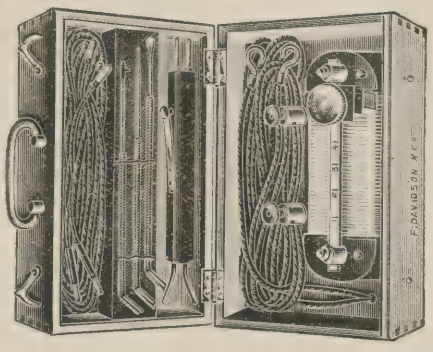
The final accounts could appear in the form shown in Table III.

In a succeeding article the Income-tax assessment, deductions, allowances, and reliefs will be explained, apart from the manner in which the accounts have been kept, so long as figures are ascertainable showing amount of profit.

New Inventions.

AN IMPROVED CAUTERY.

THE accompanying illustration shows an apparatus which has been designed for cautery work, and consists of a rheostat, handle, cords, terminals, and three heavy platinum burners. The source of electric



supply is the accumulator of a motor-car; the accumulator is, of course, continually charged by the dynamo. The cords attached to the rheostat are hooked to any accumulator from 4 to 12 volts. If more than one separate accumulator is fitted to a motor-car, one could be lifted out of its box after disconnecting and used with the outfit.

Mr. Davidson, of 29, Great Portland-street, W., has made the instrument for me.

CHARLES S. THOMSON, M.D., D.P.H.,
Medical Officer of Health, Deptford.

Reports and Analytical Records.

BICREOL BRAND BISMUTH CREAM.

(BURROUGHS WELLCOME AND CO., SNOW HILL BUILDINGS, LONDON, E.C. 1.)

THE employment of bismuth in venereal disease has been on trial for a number of years, and considerable experience has been put on record as to the influence exerted by trépol and neo-trépol upon syphilitic symptoms. In Bicreol Messrs. Burroughs and Wellcome supply the medical profession with a cream which consists of pure metallic bismuth in an extremely fine state of subdivision incorporated in a creocamph basis, each c.cm. containing 0·15 g. of the active element. Considerable interest is to-day focused upon bismuth as an anti-syphilitic agent, the metal having been reported successful in cases which had previously resisted mercury and arsenic, the attendant disadvantages being comparatively slight. In the English edition of Prof. Poulsson's Pharmacology, edited by Prof. W. E. Dixon, only a mild form of stomatitis is alluded to as a possible inconvenience.

FIVE NEW PREPARATIONS.

(1) IODO-BISMUTHATE OF QUININE (FRAISSE). (2) SÉRUM NÉVROSTHENIQUE (FRAISSE). (3) SÉRUM FERRUGINEUX (FRAISSE). (4) NATIVELLE'S TABLETS QUINIDINE SULPHATE. (5) SIROP FAMEL.

(MESSRS. WILCOX, JOZEAU AND CO., 15, GREAT ST. ANDREW-STREET, W.C. 2.)

WE have received from this well-known firm of foreign chemists specimens of five of the latest preparations which they have placed on the market, the first three being from the laboratories of M. Marius Fraisse and Co., 8, Rue Jasmin, Paris, the fourth from the Laboratoire Nativelle, 49, Boulevard de Port Royal, Paris, and the last from the laboratory of M. P. Famel, 20 and 22, Rue des Orteaux, Paris. (1) Quinine-iodo-bismuthate ampoules (Fraisse). These spirillicide ampoules, which are supplied with the proper syringe where required, and with full instructions as to dosage and administration, would enable a systematic course of the drug to be taken with safety. Each ampoule contains quinine-iodo-bismuthate, 3 gr. to 4 c.cm. of olive oil. (2) Sérum Névrosthenique ampoules (Fraisse). This preparation is a combination of strychnine and phosphorus for employment in neurotic conditions, under the prescription of a medical practitioner. Each ampoule contains 0·0005 g. strychnine cacodylate and 0·1 g. sodium glycophosphate per cubic centimetre of liquid, so that an adult may receive daily an injection of 1 c.cm.—that is to say, the contents of an ampoule. (3) Ferrugineux ampoules (Fraisse). The formula of these ampoules, which have been designed for the intensive treatment of anæmia, is as follows: Cacodylate of iron, 0·01 (1/6 gr.); cacodylate of strychnine, 0·0005 g. (1/120 gr.); and sodium glycero-phosphate, 0·1 g. (1½ gr.). The method of employment recommended is 1 ampoule daily for ten days to a fortnight, an interval of five or six days being allowed to elapse if it is necessary to recommence the treatment. (4) Quinidine sulphate tablets (Nativelle). These tablets are supplied under the name of quinicardine, in sealed tubes, at the price of 6 francs each tube, containing 20 tablets, all care having been exercised to render the drug absolutely pure. (5) Sirop Famel. This is a well-known remedy for giving relief to patients suffering from bronchial irritation and catarrhal respiratory conditions. It would appeal to medical men as a more valuable remedy if the claim set out with it were not so all-embracing, but there is considerable clinical experience in France to the effect that the sirop is a well-tolerated preparation of creosote. The creosote in the sirop is associated with codeine and aconite, so that the preparation ought not to be taken without medical advice or in doses larger than those indicated in the directions.

THE LANCET.

LONDON: SATURDAY, JANUARY 5, 1924.

SIR DONALD MacALISTER.

WE are speaking for the whole of the medical profession in offering warm congratulations to Sir DONALD MACALISTER, President of the General Medical Council, upon the honour of a baronetcy which he received this New Year's day. In the case of so well-known a man there is no need to detail the events of a career which from boyhood at Aberdeen, through Cambridge, Oxford, London, and Glasgow, has been marked by the highest academic prizes attainable. Balliol scholar at Oxford, and Senior Wrangler at Cambridge, President of the General Medical Council and of the Gypsy Lore Society; finished scholar in half a dozen modern languages; first Croonian Professor of the Royal College of Physicians of London and Principal of the University of Glasgow—such are sufficient indications of the wide range over which Sir DONALD MACALISTER has been able, in a life of extraordinary intellectual fullness, to use his mind aptly and his judgment wisely, shrewdly, and impartially.

In this place we refer only to Sir DONALD MACALISTER'S work as President of the General Medical Council, regarding his labours here as the outstanding achievement of his career. He became President of the Council in 1904 in succession to Sir WILLIAM TURNER, having previously been a Member of the body for five years as the representative of the University of Cambridge. At his election as President there were many members of the Council of far longer standing, some of whom were at that time more widely known in the purely medical world; but in the Council MACALISTER had made his mark from the beginning, especially by resolute watchfulness over the educational curriculum as conducted by various of the statutory bodies. His motions in respect to the irregularity of the conduct of examinations at the Apothecaries' Hall, Dublin, to the low standard of the early tests at the Society of Apothecaries of London, and to the impractical character of the final tests at the University of Oxford led to his appointment to represent the Council at a conference with the Board of Education, as well as to a general stiffening of the procedure at the visitation by the Council of the various examining centres. Further he became Chairman of the Pharmacopœia Committee, and thus along two of the main divisions of the work of the Council revealed himself as a leader, a reformer, and a reasonable man. So when he was elected President of the Council there was satisfaction within the body, and this was widely reflected among medical men without, who had reason to feel that the Council required, in view of increasing educational and social developments, a man equipped to deal firmly with large things, while equally able to see that in details the course taken must be correct.

These expectations have been fulfilled, and a review of the extended work done by the Council during Sir DONALD MACALISTER'S long period of authority would prove this entirely, as would any synopsis of his individual share in the proceedings. Throughout his whole term of office the Council has steadily increased in public esteem and in public utility; foolish bickerings and personalities have ceased; the finances, once sorely depleted by the needless protraction of the sessions, have been placed on a sure footing; subcommittees, wisely chosen, have rendered reports in advance on all the main headings of the work, with the result that the discussions by the main body have been coherent and well-directed. The voice of the Council, where medicine is concerned in the conduct of public affairs, is now received with respect in the transaction of national business, while the good men whom the President has led during the past 18 years would be prompt to allow that their virtues have had full opportunity under his guidance.

BACTERIAL FOOD CONTAMINATION.

A SYSTEM which depends on a sequence of slow extensions and developments instead of on the sudden application of a thought-out and comprehensive code is liable to present surprising lacunæ. Such a system we see in our laws and enactments relating to public health, and one of the most obvious of the lacunæ is in regard to the protection of certain of our food-supplies from bacterial pollution. In some directions the safeguards are very efficient, in others they are inadequate or non-existent. Dr. C. E. GODDARD [1] has recently drawn attention to the dangers of bacterial contamination from the sale of bread delivered without wrappers, of fruit—grapes, dates, and others—without any protection, while the numerous articles in grocers' shops which attract flies and which are not protected from them form other risks, the same being said of the fingering of meat in butchers' shops. As medical officer of health for the Wembley area, which includes the British Empire Exhibition 1924, Dr. GODDARD will be brought in contact with food problems of great importance. While many such sources of food pollution might be cited it is perhaps easy to exaggerate their significance in respect of public health. They form serious defects in our methods of food distribution, but of considerably greater importance is the absence of adequate control over the preparation and of subsequent care in respect of what may be called "prepared meat foods" and the lack of supervision over those who handle foods destined for consumption by the public.

A study of outbreaks of food poisoning shows that a material proportion, indeed, a majority, of such outbreaks are due to specific contamination of made-up meat foods—sausages, brawn, meat pies, and the like. There is, however, no special supervision authorised in any of our public health laws either for the premises where these are prepared or for the care of these products. The clauses in the different Acts dealing generally with food allow for inspection and seizure of foodstuffs found unfit for consumption, but such regulations do not go far enough, and there is nothing to prevent preparation under manifestly unsatisfactory conditions. These comestibles need *special* supervision and this they do not receive. It is not uncommon for such made-up foods to be prepared in or immediately adjacent to the slaughter-house and for the workers in the latter to take part in the preparation of the foods. At the City of Liverpool special powers have been obtained to control the premises

[1] Journal of State Medicine, December, 1923, xxxi., 585.

we are considering, but such enlightened authorities are very few in number. It is not the large scale manufacturers for whom such supervision is required, for here nearly all concerned are alive, if only for the preservation of their own good name, to the importance of cleanliness. The risk mainly operates for the small businesses carried on by two or three people, ramifying often into several branches concerned in slaughtering, in food preparing, and in sale over the counter. These businesses are inadequately controlled, and it is here that an immunity from accident fosters a disregard for dangers of which lack of education as to food contamination precludes any grasp.

The importance of supervision over those who handle food destined for consumption in public places is better recognised in the United States than in this country, and in New York, Kansas City,[2] and other places which might be enumerated, special examinations of these "food handlers," as they are called, are undertaken and special ordinances are promulgated for their supervision and control. The considerable number of such persons found to be suffering from syphilis, tuberculosis, and other communicable diseases is disquieting, and at the same time furnishes abundant justification for such examinations. The Health Commissioner of Kansas is endeavouring to institute a mental test for food handlers which will necessitate study of elementary sanitary principles. In this country but little has been attempted along these lines. Quite recently the case of a man suffering from advanced tuberculosis while continuing to deliver milk and otherwise take part in the duties of a purveyor of milk aroused some comment in the public press. It was not at all an isolated case and the authorities are in no way authorised to stop such a practice—as far as Acts of Parliament go they are powerless.

With such a series of ways in which disease can be conveyed by contaminated food it is desirable and important to seek for guiding principles as to the lines which should be followed if adequate protection is to be ensured. Two such principles are indicated by the facts of the situation. In the first place, with our elaborate system of public health officials the public have a right to assume that those who minister to their wants in public places where food is supplied are healthy or, at least, not likely to contaminate with harmful bacteria the food they serve. In the next place available scientific knowledge shows that it is imperative that all made-up foods which are composed of substances which favour bacterial growth should be adequately controlled and supervised so that these dangers may be minimised. This is especially necessary when such food is sold cooked and is therefore eaten without the safeguard of additional cooking. These goods are nutrient media for bacteria and the importance of the fact that there is no subsequent cooking is frequently lost sight of or unappreciated. Comparing bread and brawn, both receive no subsequent cooking, but with bread the risk of disease conveyance owing to the food being unwrapped is comparatively slight though the dirtiness implied is revolting. But with such a substance as brawn bacterial contamination is a danger because of the facility for bacterial multiplication after chance contamination and before consumption. A better protection of all food articles exposed to sale is desirable, as Dr. GODDARD wisely points out, and the prime needs are for control over those who handle food supplied in public places to be eaten without further cooking and in particular an extension of the present inadequate control over all places where made-up foods are prepared which are suitable bacterial media and which are eaten without further cooking.

[2] See THE LANCET, 1922, ii., 679, and 1923, i., 778.

CHOOSING A PROFESSION.

WE have never far to look for an example of a square peg in a round hole—a fellow-being who has missed his vocation in life. The war jerked many square pegs out of round holes, and sometimes found square holes for these pegs, but the process was seldom more than a blind shuffle. Some, perhaps many, of the misfits we see about us could have been avoided had the persons concerned had the benefit of expert medical advice at the outset of their careers. Without it, they have remained in their ill-adjustment, striving against it, what time their friends have hammered hopefully on the square peg, trusting that it would become round or that the hole would become square in the process. A very remarkable book[1] has been published by the oculist Prof. H. LAUBER, who has chosen as his collaborators 11 eminent specialists with wide experience of the misfits in life in their various specialties. Prof. LAUBER had hoped to induce the Austrian Ministry of Health to take up this work, but the fact that it has had to be carried out as an independent undertaking may have added to, rather than detracted from, its usefulness. From time to time the daily papers contain correspondence with the heading: "What Shall We Do with Our Boys?" But it has seldom been suggested that, before an answer to this question is attempted, a boy should be given a searching examination of body and mind by a medical expert or, better still, several medical experts. There is something ironical in the fact that at the present time medical examinations for certain services, such as the army and navy, are, at any rate partly, intended for the rejection of unsuitable applicants. Might not medical examinations of our fellow-beings on the threshold of life fulfil a higher purpose if their chief aim was to find out the qualifications, rather than the disqualifications, of the individual for a certain vocation or profession? Merely to pick out the "A-ones" for certain duties and to leave the remainder to fend for themselves is assuredly a policy as short-sighted as it is callous. This policy may, perhaps, appeal to a certain class of employer, but with the progress of civilisation we are learning to think in terms of the employees.

As an oculist, Prof. LAUBER has had exceptional opportunities for observing the tragedies which an unwise choice of profession brings in its wake, and he refers to the case of a cavalry officer whose high degree of hypermetropic astigmatism greatly impaired his efficiency. As a prospective cadet he had been rejected on account of his eyesight, but his father, who had influence in high quarters, got his son into the cavalry through a back door. There he was a square peg in a round hole, with no one but himself and his father to thank for his unhappy fate. Even this extreme example can be paralleled in this country and not seldom, while less obvious unsuitability for the selected career strikes the eye daily. But in the advice as to the choice of a profession the medical examiner must look far ahead; a candidate may be qualified to fill a post satisfactorily at the present, but will he be equally qualified a decade or two hence, when it is too late to change

[1] Handbuch der ärztlichen Berufsberatung. Edited by Prof. H. Lauber. Vienna: Urban and Schwarzenberg. 1923. Pp. 586. Swiss francs 18.75.

to another profession? A waiter with progressive myopia may for some time be able to carry out his duties satisfactorily without glasses—somebody else can make the pun for us—but when the time comes that spectacles are indispensable he must cease, it appears, to be a waiter. We are assuming that a waiter may never, or almost never, wear glasses, because a waiter so reinforced is as rare as, say, a High Church clergyman with a moustache. A generation ago the family doctor was often called on to advise in the choice of a profession for the son of the house, and the advice given was often sound. But with the development of the school medical service it is the school medical officer, rather than the family doctor, who will play the most important part in this matter as far as the working classes are concerned; and Prof. LAUBER anticipates the time when the school medical service will be so organised that the scholar when he leaves school will have his qualifications and disqualifications carefully analysed and classified. It is not, of course, Prof. LAUBER'S intention to rob the parents or their children of their freedom of choice; what he proposes to supply them with are scientific data on which they can base their choice of a profession.

In a chapter on Character Defects in the Young, one of Prof. LAUBER'S collaborators, Dr. ERWIN LAZAR, draws attention to the special qualifications of the hyperthymic[2] person whose bright and cheerful temperament is most suited to busy surroundings and free intercourse with strangers. The hyperthymic individual is suitable for employment in public-houses, the barber's shop, and trade generally. But he is not suitable for occupations requiring conscientious and persistent effort, nor is he fit to work alone and not under observation. The antithesis to this type is the depressive, intolerant, morose person who does not love companionship, preferring his own company. To give him the occupation suitable for a hyperthymic person is to court disaster, whereas he is comparatively well qualified to work independently and alone. Several of Prof. LAUBER'S collaborators have tabulated their information for ready reference, lists being given of various occupations and the qualifications and disqualifications therefor. Lists are also published of the disqualifications and defects most likely to give trouble in certain occupations, and to give an illustration of the thoroughness with which this work is done we would refer to a table in which Prof. GUSTAV ALEXANDER classifies the occupations unsuitable for anyone with abnormal labyrinthine functions. About 50 occupations are mentioned, and not only the acrobat and aviator, but also the chauffeur, house decorator, and jockey are mentioned in this list. The qualifications and disqualifications of a doctor are discussed by more than one of Prof. LAUBER'S collaborators, and conditions regarded as disqualifications for the practice of medicine include chronic catarrh of the respiratory passages, perforation of the septum of the nose, ozæna, psoriasis of the nails, eczema, syphilis, idiosyncrasy to mercury, degenerative defects, psychoses, and much else. History is full of records of successes achieved by square pegs in round holes, and we need only cite the case of NELSON, who was always sea-sick in rough weather, to stress the fact that apparently serious obstacles to success in a profession may be overcome. But these are exceptions proving the rule, and we should do well to fit our offspring into the mosaic of life with even greater care than we fit a piece of painted wood into a jig-saw puzzle.

[2] From θῡμός the principle of life, not θύμος the gland.

RESEARCH AND THE PRIVATE PATIENT.

IN a book dealing with the metabolism of diabetic patients[1] E. P. JOSLIN pays tribute to the great assistance he has received from the patients themselves in the course of his investigations. "The patients considered themselves united in a partnership, having for its object the accumulation of knowledge for the benefit of all diabetics rather than for the given individual under investigation in particular," he writes, and this happy experience has been shared by many whose work has brought them in touch with the modern treatment of diabetes. Its gravity and the importance of meticulous attention to details of dietary make this disease peculiar in that the close coöperation of the patient is essential for successful treatment; but the benefit to medical science which results from such coöperation might, we feel, be extended by a much wider application of such coöperation in the case of sufferers from many serious diseases. The last century saw a tremendous growth of medical knowledge resulting, on the clinical side, from the careful observation of large numbers of cases. Our knowledge of the clinical aspects of nephritis, as an example, is largely the result of the generous action of the colleagues of RICHARD BRIGHT, who placed a whole ward at his disposal to enable him to make close study of this malady. To-day, both on the clinical and the laboratory side, there is need of more detailed study of individual cases, sometimes over very long periods.

It is here that the private patient may be of such special utility. Physicians and surgeons attached to the great general hospitals are constantly confronted with the difficulty of tracing the end-results of treatment; the most elaborate "follow-up" systems fail to trace an appreciable percentage of cases; the illiteracy, the indifference, and often the stupidity of that floating population which is treated in these institutions are a formidable bar to progress. Private patients, on the other hand, can usually be traced with ease; they are accessible over long periods, and their superior education renders them much readier to supply that information which is often of vital importance in a clinical inquiry. We have heard it urged that the confidential relations between a physician and his patient prohibit the publication of data accumulated in the course of his private practice. For such a view we can find no logical support. Clearly no doctor has the right to disclose the identity of his patient in any written account of a case, and the difficulty here is far greater with private than with public patients, but the duty is imposed just as strongly in the case of hospital patients as in that of those seen in private. But provided that this first rule of conduct be observed it remains the duty of the medical man to advance knowledge, and the publication of careful clinical and laboratory observations remains the most important road for such advance.

A further benefit accruing from coöperation with the patient is the educative effect of such combination. A large part of the public remains in deep ignorance of the importance of research, and the veil of this ignorance is most surely lifted by personal experience of the methods and aims of our profession. Knowledge of the purport of laboratory investigations gives the patient an entirely new sympathy towards such work, and the laboratory worker who is able to investigate an intelligent patient over a long period is in a position to obtain results of far greater utility than is the case when a single observation is all that is permitted to him.

Annotations.

"Ne quid nimis."

THE NEW YEAR HONOURS.

THE list of New Year honours, although short, includes the names of 14 members of the medical profession. Sir Donald MacAlister becomes a baronet. Among those upon whom knighthood is conferred are Dr. Henry William Russell Bencraft, of Southampton, well-known alike as a sound practitioner, now retired, as a sportsman, and politician; Dr. Byrom Bramwell, a great physician and teacher, recently honoured by his colleagues and friends on the occasion of his seventy-fifth birthday; and Dr. Harry George Waters, P.M.O. of the East Indian Railway. Dr. Henry Lindo Ferguson, Dean of the Faculty of Medicine, Otago University, Dr. David James Galloway, member of the executive and legislative councils of the Straits Settlements, and Lieut.-Colonel William Thomas Prout, one of the medical advisers to the Colonial Office, also become knight bachelors. In the Military Division of the Order of the Bath Lieut.-General Sir William Boog Leishman, K.C.M.G., Director-General of the Army Medical Service, becomes a knight, and Major-General Dennis Joseph Collins, C.M.G., Deputy Director-General in the Southern Command of the East Indies, and Air-Commander David Munro, C.I.E., of the Royal Air Force Medical Services, Companions of the same Order. In the Royal Victorian Order Surgeon Lieut.-Colonel Sir Warren Crooke-Lawless, C.B., C.I.E., C.B.E., is made a knight, and Dr. Alexander Hendry, Surgeon Apothecary to H.M. Household at Balmoral, is promoted from M.V.O. to C.V.O. Dr. Behari Lal Dhingra, Chief Minister of the Jind State, Punjab, receives a Companionship of the Indian Empire, and Dr. Louisa Helena Hart, medical missionary at Madanapalle, Madras, receives the Kaisar-i-Hind Medal. To all these we offer in the name of the medical profession our hearty congratulations.

A FRENCH MEDICAL COUNCIL.

THE note by our correspondent in Paris, which appeared on p. 1318 of our issue of Dec. 15th, 1923, in regard to a proposed Medical Council in France, is of much interest. It suggests the establishment in France of what at first sight might seem to be a body analogous to our own General Medical Council, but this would be a wrong idea of what is so far projected, in spite of certain similarities of design and function. It appears that local councils are to be established for dealing with conduct in a professional respect. These appear to resemble in some degree the committees of inquiry set up under the Insurance Acts in this country to deal with offences under those Acts. This will no doubt be of considerable help in checking abuses, but there is always a risk with local tribunals that personal factors may not be eliminated, and that the judicial aspect may be to some extent overlooked. It is understood, however, that in addition to this there is to be a National Medical Council sitting in Paris, of whom half are to be legal members and half members of the medical profession, with the President of the Academy of Medicine as president and member ex-officio. To this body appeals from the local tribunals can be made, and a safeguard is therefore provided against any local prejudice. The details of the working of this Council are not set forth in the note, and there is nothing to show whether there is power to summon witnesses, or to take evidence on oath. The right of appeal is set down as being in regard to charges of incompetence, exceeding of duty, or violation of the law. The first and last of these are not matters which would come before the General Medical Council of the United Kingdom. The first is a matter with which it never deals, leaving persons who feel themselves aggrieved to take what action they think well in the civil courts. The term "exceeding of duty" is not very clear, and it is difficult to say what is meant by it. Violation of the law in this country would be dealt with in the first instance by the civil courts, but the General Medical Council has the duty laid upon it of considering convictions and judging whether the gravity of the offence is such as to warrant the erasure of a name from the Register or not. There does not appear to be any provision for either the local council or the National Council to deal with offences which in this country come under the heading "infamous conduct in a professional respect," and include offences for which no civil remedy is provided. In view of the long experience of the General Medical Council and the large number of recorded judgments which appear in its publications the authorities in France might do worse than to consult the Council, and, if necessary, to ask for its observations before any new law on this subject is finally settled.

THE CONTROL OF ALCOHOL.

Dr. Arthur Shadwell has long been known as a leading student of the drink problem and more especially of the possibilities of keeping its evils within bounds by legislative measures. His writings on the subject are remarkable—one is almost tempted to say unique—because he seems really to occupy that detached and impartial position which every brewer and equally every teetotal fanatic claims as his own. He has just published a volume,[1] written originally as one of the war monographs to be issued by the Carnegie Fund for International Peace, which gives a detailed history of the controls which gradually restricted the facilities for getting drink during the war and of their partial relaxation since 1919; in an appendix of 82 pages are printed a selection of the orders and regulations which were made and a variety of statistics. The effect of these various measures cannot, of course, be stated in such objective terms, but the author has no hesitation in affirming his conviction that the police returns give in a general way a satisfactory gauge of alcoholic excess, especially where, as in the present instance, the fluctuations are so large. Whether the scale is the consumption of alcohol (which is at one end of the series of possible measures) or convictions for drunkenness (which is the other end of the series), there is no doubt that the imposition of control was followed by less drinking, and that drinking became progressively less as control was made more stringent. The consumption of beer in 1914, 1918, and 1922 was as 100, 38, and 65, of spirits as 100, 28, and 54; the convictions for drunkenness as 100, 16, and 42.

There is much of interest in the details of the statistics—the seasonal and local changes and so on—but most readers will probably prefer to treat them in the broad way which the author encourages and turn to the chapter in which he summarises the results which he deduces. These are four in number: (1) While engineering, shipping, and other vast industries had to be dealt with because they were *useful* for the conduct of the war, alcohol was the one thing which had to be dealt with because it *interfered with* the conduct of the war. Drinking was found to be a serious national disability and remains so. (2) It is possible effectively to check excessive drinking by legislative control which leaves an amount of liberty sufficient to prevent substantial resistance or evasion. (3) The chief measures in producing this result were shortening of hours, limitation of supply, diminution of strength, and raised prices. (4) It is possible under peace conditions to keep the volume of intemperance far below its old level by means of shorter hours and higher taxation. And as corollaries we may particularly notice three points which Dr. Shadwell insists on. Control will reduce consumption only to a

[1] Drink in 1914–1922: A Lesson in Control. By Arthur Shadwell. London: Longmans, Green and Co. 1923. Pp. 245. 10*s*. 6*d*.

certain point: if it is pushed too far or too fast those who are controlled will rebel, as they did in Sweden in 1918. And the sheet-anchors of control are short hours and high cost. These have proved really efficacious, while State ownership, reduction in public-houses, improvement of premises, disinterested management, and similar devices have failed to exert any perceptible influence on sobriety and public order. This last conclusion will distress those who believe that the quantity of alcohol drunk is of less moment than where one drinks it, and that a man will probably drink less in pleasant and humane surroundings than in a gin-palace. Popular opinion on the reformed public-house is apt to be misled by its manifest advantages for those who do not want alcohol. Those who imagine that the standard of the tea-room is reproduced in the bar should study the author's full account of the Carlisle experiment; whatever other benefits it conferred on the inhabitants, it is difficult to see any evidence that it reduced intemperance to a greater degree than did the restrictive measures which prevailed in the controlled areas generally. Finally, Dr. Shadwell flatly denies that the reduction of drunkenness which obtains at present is due to any general tendency towards sobriety—to that change of heart on the subject which has to some people been the most hopeful sign of permanent and lasting improvement. He admits that such a tendency exists, but thinks that its action is very slow and perceptible only over a long period of years.

The book deserves, and will, we hope, receive, the careful attention of everyone who is concerned in framing temperance legislation. Short cuts might be simpler in the end. It is possible that Benjamin Kidd might have been able to convince Dr. Shadwell that a will to power can make social evolution travel at an extraordinary pace. But the author's plea to drop polemics and give common-sense and coöperation a trial is one which by its sheer reasonableness must receive respect. And he shows plainly that much may be achieved by such characteristically national methods.

KÜMMELL'S DISEASE.

IN a paper read before the Section on Orthopædic Surgery at the seventy-fourth annual session of the American Medical Association, Dr. Fosdyk Jones,[1] of Denver, who reported an illustrative case, stated that the post-traumatic spondylitis described by Hermann Kümmell (Hamburg) in 1895 is a rare but distinct clinical entity caused by direct or indirect injury to the vertebral column. Kümmell described the following three distinct stages in the condition: (1) The stage of initial injury to the spinal column attended with a varying degree of surgical shock, (2) the stage of relative comfort in which the patient is able to carry on his occupation, and (3) the stage in which after several weeks or months, or even two or three years, an angular kyphosis develops with recurrence of pain, which is either localised over the spine or radiates over the extremities. Fracture does not always result from the injury, but in some instances severe contusions of the spongiosa are sufficient to damage the bony framework and cause slow and gradual collapse of the spinal segments. X ray examination, in which both antero-posterior and lateral views are essential, may not show any obvious lesions in the early stage, whereas after months or one or two years the collapse of the vertebral bodies and compression of the intervertebral discs is plainly seen. The diagnosis must be made from Pott's disease, spinal neuroses, contusions, ankylosing spondylitis, back strains, and railway spine. The prognosis as a rule is favourable if early treatment is instituted. The deformity can be controlled by a suitable immobilising apparatus or closely fitting plaster-of-Paris jacket, and fibrous or bony ankylosis can be obtained which will give an excellent functional result. In the more severe types, especially neglected cases, a radical ankylosing operation, such as that described by Hibbs or Albee, is indicated. Dr. Fosdyk Jones's case, which occurred in a boy aged 5, is of special interest in that though the disease may follow injury at any age, it is rarely seen in children, and this was the youngest patient on record in whom it had been observed. The condition occurred as the result of a fall, directly after which the boy remained unconscious for five or ten minutes and then complained of severe pain in the back and thighs. He was kept in bed for two days and then allowed up. A week after the injury a swelling was seen over the lumbar region, but disappeared in a few days after the use of hot compresses. Two months after the accident he complained of severe pain in the back radiating to the thighs, and movements of the spine, especially in a forward direction, were very painful. An angular deformity in the region of the lower lumbar vertebræ was then noticed. There was no paralysis. A clinical diagnosis of Kümmell's disease was confirmed by X ray examination, which showed a compression fracture of the fourth lumbar segment with thinning and compression of the intervertebral discs. A plaster-of-Paris jacket was applied and the pain disappeared. As no increase in the kyphosis took place, an ankylosing spinal operation was not considered necessary.

THE RELATION OF MALARIA TO ALTITUDE.

THE relative rarity of malaria in elevated regions in the tropics has been recognised since the very earliest times, but up to the present no precise observations seem to have been made on the influence of altitude upon malaria. S. R. Christophers has stated that the highest point above sea-level at which indigenous malaria exists is Quito, a town situated on the Equator at a height of 9000 feet, but possessing an even and warm climate. Malaria is prevalent sometimes at 5000 feet in the Himalayas, and at still higher levels, up to 7000 feet, in Southern India. In Italy indigenous malaria is said to occur at an altitude of 8500 feet. The consideration of these facts has led Lieut.-Colonel C. A. Gill, I.M.S., to make more exact observations in the Punjab, and his results are published in the *Indian Journal of Medical Research* for October, 1923. A spleen-rate of 80 per cent. is found at an elevation of 1000 feet, and at the foot of the Himalayas from 2000–4000 feet endemic malaria is very severe. The infection appears to be constant, and this region is not liable to experience the great epidemics which periodically decimate the people of the plains. From 4000–5000 feet endemic malaria appears to be less prevalent and relatively milder in character. The highest elevation in the Himalayas in which indigenous malaria has so far been found is at a height of 5000–6000 feet, while at the hill-stations, which lie from 6000–8000 feet, such as Simla, Kasauli, and Murree, malaria is entirely absent. Epidemiological observations made at the last-named station show that ten species of anopheles, six of which are known to be capable of transmitting malaria in other parts of India, are prevalent. The absence of malaria cannot therefore be ascribed to the paucity of suitable mosquitoes, nor to any deficiency of carriers of the malaria parasite, as 80 per cent. of the summer population, who are temporary residents in this hill-station, come from the endemic centres of the disease.

Climatic factors necessarily play a part. The mean temperature is markedly lower throughout the year as compared with that of the plains. The daily temperature shows a mean range of 10–20° F., the maximum never rising above 80°, while the minimum may fall at certain times of the year to below 40°. Should the minimum temperature at which the anopheles parasite is capable of developing be taken at 61° F., it will be seen that the atmospheric conditions in Murree are suitable for the spread of this disease for at least five months in the year, and hence the absence of indigenous malaria cannot be attributed to any adverse influence exercised by temperature during this period. The experience of the author in other parts of the world

has led him to believe that the humidity of the atmosphere is the chief factor in determining the development of the parasite within the mosquito, and the most striking feature exhibited by the meteorological chart of Murree is the dryness of the atmosphere throughout the greater part of the year. The relative humidity is greatest during the coldest months, and in May it is only 41 per cent. Should the mean relative temperature at which this development can take place be estimated at 63 per cent., it follows that the potential infection period is reduced in this instance to one of eight weeks. To test this point still further, experiments on the transmission of malaria were undertaken with the local anopheles, especially *A. willmori*, and it was found that development takes place when the temperature remained constant—at about 68° F.—with a relative humidity between 79 and 94 per cent.—that is, under the atmospheric conditions which prevailed in Murree during the months of July and August. The absence of malaria in these hill-stations must therefore be ascribed to the very short period during which the infection may be acquired, and this, at the most, does not exist two months.

METABOLISM OF SKI SPORT.

FROM time immemorial the Scandinavian peoples have used skis (Icel. *scidh*, a piece of wood) to prevent them from sinking in the snow on their journeys in the long Northern winter. Ski-ing as a sport is about 60 years old in Norway, whence it was introduced into Switzerland about the year 1900. The last ten years have seen an enormous development of ski-running as a form of winter amusement, and it has now become the object of serious study by physiologists. Prof. A. Loewy has recently published in the *Schweiz. med. Wochenschrift* the results of a study undertaken by him to ascertain whether the sensation of ease experienced by the ski-er necessarily involves a diminished output of energy, and whether ski-ing is superior to walking from an economic point of view, as Liljestrand and Stenström had previously found to be the case with skating and L. Zuntz with cycling. An unskilled ski-runner obviously expends a great deal of unnecessary energy in various balancing and other movements of the body, whereas the movements of an expert are not only fewer in number but are also easier and freer, giving the impression that less energy is needed to cover a given distance with skis than without them.

To verify this impression an estimation of the gaseous exchange is essential. The only observations on the subject hitherto published are some notes by Liljestrand, whose experiments, even though made under specially favourable conditions rarely realised, showed a higher value both for CO_2 output and for oxygen consumption. Prof. Loewy's idea was to ascertain the exchange taking place under "natural"—i.e., ordinary—conditions both with and without skis, on firm and on soft snow, on level and on rough ground. The subjects of the experiments were healthy schoolboys of from 13 to 17 years of age, all of whom were expert ski-ers. The apparatus used was that devised by Zuntz, with which the volume of inspired air could be read off, and the expired air collected and subsequently analysed. A table is given showing for each of the nine individuals tested the volume of air breathed, the CO_2 output, the oxygen consumption, and the percentage of oxygen increase with and without skis on level ground and on a slope. The figures give a good idea of the influence which the condition of the ground exercises on the breathing, but the most important point brought out is that in every case the volume of air breathed is enormously increased—up to 47 per cent.—with the use of skis. Similarly, while the oxygen consumption is much increased when walking on snow without skis as compared with walking on firm snow-free roads—17·3 c.cm. as compared with 13·5 c.cm.—yet with the use of skis it rises still more markedly, the figures in this particular series reaching a minimum of 20·6 and a maximum of 31·8 c.cm. In answer to the possible objection that the height of Davos (1500 m.), where the experiments took place, might have some bearing on these results, Prof. Loewy points out that all the subjects of the experiment were living at this altitude, and were therefore well acclimatised.

It is thus quite clear that from the point of view of expenditure of energy ski-ing offers no advantage over walking; and although in ski-ing on level ground there appears to be invariably an associated sensation of ease and lightness, Prof. Loewy has conclusively demonstrated that this subjective sensation bears no relation to the actual output of energy required, the apparently easier movement involving a considerably greater consumption of energy. The value of ski-ing, however, lies mainly in the greater speed attainable by its means, and in the possibility of moving with comparative safety over ground that would otherwise be dangerous, both these advantages amply justifying the popularity of the sport.

THE OFFICIAL CONTROL OF DISPENSING.

IN a circular (No. 462) just issued under the Sale of Food and Drugs Acts the Minister of Health draws the attention of local sanitary authorities to certain suggestions which he has received from the Society of Public Analysts with regard to the sampling of prescribed medicines. These are to the effect:

(i.) That the inspector be instructed, prior to dividing the sample into three parts, to mark, in the presence of the vendor, the height the contents reach in the bottle in which the medicine is originally supplied to him by the vendor. That the bottle so marked be submitted to the analyst in order to enable him to determine the total quantity of medicine supplied.

(ii.) That the analyst and the medical officer of health be both consulted as to the type of prescription it is desirable to use for the purpose of checking the accuracy of dispensing, and that, in the event of any substantial inaccuracies being disclosed by analysis, both these officers be consulted as to the desirability of instituting proceedings.

The object of the first suggestion is to enable the analyst to ascertain the total quantity of each of the ingredients (including the water or other "vehicle") present in the medicine. If he receives only a portion of the sample, representing an unknown fraction of the whole, he is only able to ascertain the relative percentages of the several ingredients; but if he is also provided with information as to the total quantity of the medicine dispensed he can then deduce the total amount of each of the ingredients as supplied by the chemist. These particulars will obviously be of importance to the authority in considering what action it should take in regard to a medicine which has been inaccurately dispensed. The second suggestion is in accordance with the practice already largely adopted by local authorities. It is clearly desirable that, where a sample of medicine is taken for the purpose of checking the accuracy of dispensing, it should be so chosen as to be capable of accurate analysis. It is also desirable in considering whether or not proceedings should be taken under the Sale of Food and Drugs Acts that proper regard should be paid both to the degree of accuracy obtainable in the analysis of the article in question and to the margin of error allowable in ordinary dispensing operations.

THE DIAGNOSIS UNIT ON ACTIVE SERVICE.

IN the *Journal* of the Royal Army Medical Corps for December, 1923, Dr. Philip Manson-Bahr concludes his useful contribution on Laboratory Diagnosis in the Tropics and Sub-Tropics in War Time. In this paper he calls attention to the value of diagnosis units consisting of one medical officer, two special orderlies, and two drivers. Such units have the advantage of extreme mobility; two of them, in fact, moved to Damascus in 1918 with the cavalry. They are self-contained, possess their own transport, and are able to perform essential work at a rapid rate. During the summer of 1918 six units in Palestine examined more than 40,000 slides of blood for malarial parasites,

discovering a percentage of subtertian infection which varied at the different stations from 2 to 16 and which showed a dramatic rise in the month of October. Malaria simulates other diseases so closely as to be almost undiagnosable without the help of a laboratory; at one of these diagnosis units it was found that 11 out of 15 cases segregated as dysentery and 30 out of 45 cases diagnosed as influenza were really due to subtertian malaria. For the purpose of training the personnel to deal with the diagnoses of malaria and dysentery, 7 officers and 16 orderlies attended a course, lasting six weeks, held some distance behind the line. Within this time it was possible to render the officers, and in most cases the men as well, familiar with the appearance of normal blood cells and the various stages of the malarial parasite, although, of course, the actual diagnosis was made in each case by the officer in charge. The advantage of mobile horse-drawn diagnosis units of the kind described by Dr. Manson-Bahr is apparent from his article and should certainly be borne in mind in any future campaigns. By means of such rapid diagnosis the mechanism of evacuation is accelerated, the work of the field laboratories alleviated, and the routine of the casualty clearing station lightened.

MEDICAL BIOMETRY.

Prof. Raymond Pearl in his "Introduction to Medical Biometry and Statistics,"[1] has attempted to write an introduction to the practice of statistics which shall appeal to the medical reader having no preliminary mathematical knowledge and no primary interest in mathematical lines of thought. With this end in view, mathematical investigations are almost wholly excluded from the volume, the fundamental concepts being developed on experimental lines; an excellent example of this is the chapter on correlation, where the passage from no correlation to perfect correlation is exhibited by a series of experiments. In the first chapter, the author, having dealt with preliminary definitions, lays down the following propositions:—

1. That there is no inherent reason why medicine in every one of its phases should not ultimately become in respect of its methods an *exact* science, in the same sense that physics, chemistry, or astronomy are to-day exact sciences. 2. That this goal will be reached in exact ratio to the extent to which quantitative methods of thought and action are made an integral part of the training in every sort of medicine. 3. That no number or figure can be said to have any final scientific validity or meaning until we know its probable error, the "probable error" being the measure of the extent to which the number will vary in its value as the result of chance alone.

Prof. Pearl gives an historical sketch of the pioneer work done by Graunt, Süssmilch, Quetelet, and Farr. In speaking of the latter, he makes full use of Dr. M. Greenwood's article published in our columns[2] in 1921, which he characterises as "the best existing brief estimate of the significance of Farr in the history of medicine." Following chapters describe the raw data and methods of presentation. The author's account of the Hollerith system will be found very helpful since few private students have the opportunity of seeing or using the machines. Prof. Pearl passes to an exposition of rates and ratios and a short account of life-tables. In speaking of short methods of life-table construction, reference might have been made to Part II. of the Supplement to the 75th Annual Report of the Registrar-General, which describes the method of Dr. E. C. Snow, much the best available. Prof. Pearl next discusses the concept of "probable error" and related notions of probability. In Chapter XIII., the measurement of variation is studied; in the next two, correlation; the work concludes with a short account of simple curve fitting. It will be seen that the book covers much ground, and, in our judgement, its author has successfully accomplished his task. It is natural and right that in his choice of examples, Prof. Pearl should have had the needs of American students chiefly in mind, but this fact will not prevent English public health students from profiting fully by a study of the book. Since, under the new regulations of the General Medical Council, a less superficial acquaintance with the elements of vital statistics is demanded of candidates for the D.P.H. than before, the book should enjoy a wide circulation; we know of no other likely to be equally useful to the medical student. The literary style is agreeable and the expression of opinion on disputed points temperate, with the possible exception of a footnote on p. 224, where the animadversions upon Mr. J. M. Keynes's treatise might have been expressed more courteously. We gather from the preface that Prof. Pearl has in mind to publish a sequel to this book; should it be as well written as the present volume, advanced students will incur the debt of gratitude which this book imposes upon beginners.

RECOVERY BRANCHES OF HOSPITALS.

IN reporting last week the meeting of King Edward's Hospital Fund for London, brief mention was made of the report of a committee on the "recovery branches" of London hospitals. This report was presented by the chairman of the Hospital Economy Committee, Mr. Leonard L. Cohen, who remarked that the apparent cheapness resulting from the low cost per bed at the branch was largely illusory. Four of the large London hospitals have branches wholly or largely devoted to recovery work as distinct from convalescent work. These are the Elizabeth Garrett Anderson Hospital for Women (at Barnet), the London Hospital (at Reigate and now also at Mitcham), the Royal Northern Hospital (at Southgate), and St. George's Hospital (at Wimbledon, partly recovery and partly convalescent). There is no doubt that convalescent patients benefit by the better air and the comparative quietude of their surroundings at these recovery hospitals; there is the further advantage that the number of cases passed through the parent hospital can be thereby increased. It was also thought at one time that the average cost at the branch would be much lower than at the hospital, but in respect of this financial saving the advantage appears to have been exaggerated, and any hospital which established a recovery branch on the strength of this argument might find itself involved in unexpected financial liability. The resemblances between the recovery branch and any other addition to the bed accommodation of a hospital are far greater than the differences. The addition of a recovery branch, moreover, concentrates in the parent hospital a larger number of patients who need expensive methods of diagnosis and treatment, thus enabling fuller use to be made of a highly specialised staff and apparatus. The wider adoption of the system should properly be regarded as a form of hospital extension, the additional beds merely being at a distance instead of on the hospital site. It is in fact an economical and efficient method of extension.

THE COMMON COLD.

"THE amount of absenteeism in large business and industrial establishments due to minor illnesses is seldom appreciated until the facts are thoroughly reviewed." This is the opening sentence in a recent Statistical Bulletin of the Metropolitan Life Insurance Company of New York (Vol. IV., No. 11), where an analysis is made of the loss of time due to the "common cold" among 6700 clerical employees at the company's central office. During the year ending July 28th, 1923, no fewer than 2824 common colds, involving disability for work, were reported to the company's medical staff, infection occurring at a rate of 421 per 1000 employees for the year. We are not told what degree of streaming nose determined the disability for work or whether the risk of infecting others counts more in New York than it does here as an excuse for absence. The average number of days of disability per person on the pay-roll for the year was 0·9, and

the average number of days off work per case 2·2. On the whole in this one office 6233 days were lost in the year from common colds, among which, be it noted, were generously included acute bronchitis and tracheitis. Two periods of maximum incidence were observed, the first following the advent of cool weather in the late summer and early autumn, the second during the following January or February when the coldest weather of winter prevails. This twofold prevalence suggested the occurrence of two types of catarrhal fever, possibly interrelated in some way. From a careful study of the figures it appears that in New York there is a close relation between the number of common colds and the rise and fall of the weekly mean temperature, a drop of 10° F. carrying with it an increase of 18 colds per week in this group of 6700 people. A chart reproduced in the Bulletin shows graphically the inverse ratio of colds and temperature. On the other hand, relative humidity and total precipitation seemed to have little or no influence on the incidence. The Bulletin suggests that the annual downward swing of temperature can be compensated for by proper attention to clothing, to ventilation, and to the heating of homes, work-places, and means of transportation. We need not conclude, and, indeed, the Bulletin does not imply, that the fall of temperature in itself is responsible for the infections—it may just as well be the indoor habit of life to which the drop of temperature gives rise; and it remains to be seen whether the evil would be substantially mitigated by keeping the insurance clerk all day long, at work and at play, in a uniform temperature. Experience does not suggest that those who pay most attention to warming their aura secure thereby much immunity in comparison with their less protected associates. The relationship between the two groups of minor infections is being further studied. We are glad to learn that the U.S. Public Health Service is inaugurating a study of common colds over a prolonged period. It is remarkable what little definite knowledge there is regarding the epidemiology of these mis-called minor ailments, which are the bane of civilised life and a constant menace to the prestige of medicine.

A SORDID STORY.[1]

THE publication of the story of a trial that has excited considerable emotion of an unwholesome kind in the public mind, within about 12 months from its conclusion, is open to the criticism that the time which has elapsed is too short for dispassionate and therefore impartial examination of the evidence to be possible. This latest volume of the excellent Notable Trials Series has been edited by a journalist of ability, who has not confined himself in his introduction, as some of the lawyers who have treated other criminal trials for the same publishers have done, to a judicial setting forth and summary of the facts and circumstances of the case. He prefers to criticise judge, counsel, and conclusions of the jury, mainly in order to convince us that Edith Thompson was wrongly convicted. He condemns, for example, Sir Henry Curtis Bennett, a not inexperienced advocate, for having "lost one of the opportunities of his life-time when, after the confused and uncertain opening of the Solicitor-General," he did not keep Mrs. Thompson out of the witness-box, and leave the prosecution to fulfil their admitted obligation to prove the case against her. He condemns equally the very unemotional judge who tried the case, for references to Bywaters as "the adulterer," asserting that adultery is to young people of the present day "merely a quaint ecclesiastical term for what seems to them the great romantic adventure of their lives." Mr. Young appears to us hardly to appreciate the position of a jury, who had to consider whether Mrs. Thompson, in fact, suggested and instigated the murder of her husband, which she did nothing to prevent when it took place, rather than whether she was determined, when she wrote her notorious letters, that Bywaters should stab Thompson, or believed him to be capable of doing so. However, whatever her mental reservations may have been, neither her condemnation, nor his, laid any heavy responsibility on the medical witnesses called by the prosecution. Dr. P. J. Drought, who described the wounds on the murdered man, was quite clear that the fatal wound was due to the last blow inflicted, and was of the opinion, but not positively so, that the blow was struck from behind; and his evidence, on the whole, was not inconsistent with the story which was told by Bywaters, and which was not believed by the jury, in description of how the struggle began. Mr. J. Webster and Sir Bernard Spilsbury, if they did not prove that Mrs. Thompson had never administered poison or powdered glass to her husband in order to kill him, stated that no traces of any such attempts to murder remained in the organs submitted to them. The medical and scientific evidence in the case was neither vital nor challenged, and it is not necessary to recapitulate here the history of a crime and a trial still fresh in the memory of those interested. We regret the way in which a sordid story has been presented.

THE VENEREAL DISEASE SOCIETIES: A FUSION OF WORK.

THE eighth annual report of the National Council for Combating Venereal Diseases has just been issued and covers the year ending June, 1923. While the Council has to regret a pecuniary stringency which has been common to all voluntary associations in these times of financial stress—a stringency which has compelled them both to cut down their personnel and move to smaller offices—the latest report shows that activity in propaganda has in no way been abated. The outstanding feature of the year has been a wide and also intensive dealing with venereal problems internationally, which culminated in the institution of the Union Internationale for the study of the subject, and the last report of the National Council deals fully with the objects of this new union. There is also issued with the report a précis of the important meeting held in November last at which the fusion of the National Council for Combating Venereal Diseases with the Society for the Prevention of Venereal Disease came into definite form, with the result that the British voice in international affairs will now have the advantage of unanimity in principle. It will be remembered that at a previous conference of the two bodies the following resolution had been approved:

> Subject to the approval of their respective executives this conference resolves itself into a deputation to the Ministry of Health to urge that the law should be altered so as to permit properly qualified chemists to sell ad hoc disinfectants, provided such disinfectants are sold in a form approved and with instructions for use approved by some competent authority.

It was then seen that the main obstacle to concord was about to disappear, and at a meeting last November of the National Council it was announced that both bodies had accepted the report of a committee of inquiry on the matters at issue, so that the new chairman of the National Council, Lord Trevethin, was able to state that the damage to both organisations in the eyes of the general public, due to their dissensions, would no longer be felt.

In respect of the international movement, Mrs. Neville-Rolfe, the general secretary of the National Council, attended a conference at Paris, when it was agreed that a union should be formed of all the national organisations engaged in the work of combating venereal diseases. The immediate work before this union is stated under the following headings: Rendering non-infective the maritime and colonial services; surveillance of emigration; surveillance and concerted action along the frontiers; international measures for the suppression of quackery; a single moral standard for both sexes; and to study

generally the principles of legal responsibility, compulsory notification and treatment, and penalties. There is, then, every chance that some of the gross causes of the dissemination of disease will disappear, while the voice that should be heard with particular respect, as coming from the main maritime power of the world, will lose none of its emphasis from detailed differences of opinion among honest workers.

THE WORSHIPFUL COMPANY OF PLUMBERS.

Dr. F. J. Waldo, recently Master of the Worshipful Company of Plumbers, has re-issued his little history of the Company, which makes interesting and informing reading. This history dates back through many centuries and shows how a craft guild, by tenacious effort, can maintain its organisations in the face of many vicissitudes. The Charter of James I. brings us definitely into a modern sphere of thought, for it stated that it was granted for the utility, advantage, and relief of the good and honest, and for the terror and correction of the evil, deceitful, and dishonest. The ordinances of the Company from the reign of Edward III. up to this charter are set out, together with a description of the arms of the Company, in the following phraseology of Elizabethan heraldry :—

"And whereas the most ancient and necessarye Seyence of Pluming dothe no lesse deserve to be remunerated then any other mysterye or Arte whatsoever, I the sayde Clarencieulx King of Armes by power and aucthority of my office, granted unto mee by Letters Pattent under the Broade Seale of Englande have geven graunted assigned and allowed and by their putes doo gyve graunte assigne and allow unto the sayde Companye of Plumers and theire succesors forever this theire Armes and Creast following: Vialt or on a Cheveron Sable towe soodring irons in saultor with a cutting knyfe and a shaver argent; in Cheife between two sounding leades proper, a Jacobs staffe of the seconde, and in poynt a water levell of the same. And for theire Creast upon a Heaulme on a wreath or and sable a ffountayne argent garnished on the toppe with an Archangel holding a sworde and a Ballance or with this their ancient worde or device Justicia et Pax."

As is well known, a system of voluntary registration of plumbers was inaugurated by the Company of Plumbers 40 years ago at the time of the International Health Exhibition. The Company is not wealthy, as may be gathered from the fact that its chief source of income has been derived from the sale of its hall, and it is reasonable to think that the time may have come when the registration of plumbers should cease to be voluntary and those who desire to become plumbers should pay a definite fee of registration after showing that a certain standard of proficiency has been reached. A high standard of plumbers' workmanship is necessary for the carrying on of the business of this life, as the Charter of James I. indicates, and all the public is interested in is being able to distinguish a man of competence and training from the father of Joseph Vance, and in promoting a proper system of technical education for those responsible for domestic sanitation.

THE CASE OF INSURANCE PRACTICE.

AT the Court of Inquiry into the insurance capitation fee, whose first sitting is to-day, Friday, Jan. 4th, the case presented on behalf of the insurance practitioners by the Insurance Acts Committee of the British Medical Association will run on lines which all familiar with the question have confidently anticipated. And as the arguments are sound we would not have them altered. Medical men working under the National Health Insurance Acts cannot, and do not, expect to escape the effects of financial stringency, but the medical profession has already given evidence of its willingness to make sacrifices, while the conditions of panel practice are so arduous that unless remuneration is adequate the quality of the service must be rendered less secure. The well-known places in which the services of insurance practitioners can be differentiated from the work of private practice are again set forth with great clearness and in proper perspective.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

LII.

THE PALLIATIVE TREATMENT OF TOOTHACHE.

IT often happens that an individual afflicted with toothache seeks the aid of a doctor because that of a dentist is not available. Successful relief of the pain requires a knowledge of the pathology of dental disease. Toothache or odontalgia is due to two causes: inflammation of the pulp (commonly, though erroneously, called the nerve), or pulpitis, and inflammation of the dental periosteum or periodontitis. A correct diagnosis is essential, for the treatment of the pain arising from these conditions is different.

Due to Two Causes.

Pulpitis usually arises as a sequel to dental caries, though it may follow occasionally from other causes, such as fracture of a tooth. The pulp is a delicate and complex structure containing an abundance of nerve fibres and blood-vessels, which enters the tooth by a narrow opening at the end of the root. The cavity in which the pulp lies, being formed of dentine, is rigid. Thus in hyperæmia of the pulp the dilatation of the vessels occurs at the expense of other elements of the pulp, and is most marked at the constricted entrance. This serves to explain the severe pain of pulpitis and the reason why suppuration and gangrene so commonly occur; the delicate nature of the pulp and the anatomical factors allow of only a limited power of repair. The pain is sharp and shooting; it tends to occur in acute paroxysms which may suddenly cease, and is usually worse at meal-times, for food gets jammed into the cavity and increases the tension. Thermal changes affect the pain. Sometimes cold will relieve it in the early stages by constricting the blood-vessels; later both heat and cold intensify it. Chemical stimuli (sweet and acid substances) may increase the pain, possibly by altering the osmotic tension in the pulp. The pain is usually more severe when the patient lies down. If the pulp is actually exposed at any point, pressure on this exposed area causes excruciating pain. Even cotton-wool pressed lightly in the cavity causes suffering out of proportion to the pressure used. In the later stages, when suppuration has commenced, the pain becomes worse and throbs; it may not be localised in the tooth which is the cause, but may be referred to any other tooth on the same side, even from a lower molar to an upper. In such a case a painful stimulus applied to the lower tooth may cause an immediate exacerbation of pain referred to the upper. The pain may be referred to other areas supplied by the fifth nerve, and, in addition, there may be associated areas of hyperæsthesia of the skin of the face, which have been mapped out by H. Head.

Periodontitis.—The periodontal membrane is both a supporting and nutritive structure. Its fibres are attached to the root and to the bone of the socket; thus it is the means of attaching the teeth to the jaw. The membrane is well supplied with blood-vessels and nerves. Although the periodontal membrane is frequently infected via the gum margin, as in pyorrhœa, the inflammation rarely gives rise to pain, for the pocket formed by the progressive ulceration from the surface allows of drainage and prevents tension. When the periodontal membrane is infected via the pulp canal following gangrene of the pulp, pain is common. A normal tooth is capable of slight movement in all directions through stretching of the fibres of the periodontal membrane. This buffer-like action of the membrane lessens the impact of mastication. In periodontitis the engorgement of the vessels causes the tooth to rise slightly in its socket, the

first symptom being a slight persistent soreness, which is increased when the teeth meet. The tooth feels longer than its neighbours; indeed, it *is* longer, and thus the whole force of mastication falls on the inflamed tooth. At this stage gradual pressure on the tooth may bring relief by emptying the vessels, though a sudden impact is painful. As the inflammation increases and the tissues become filled with exudate, the tooth rises higher in its socket and becomes perceptibly loose. The pain assumes a dull, boring character, and the slightest pressure on the tooth increases it. Thermal changes do not affect the tooth, nor does pressure in the cavity increase the pain, except through pressure transmitted to the membrane. The gum over the root becomes red and tender. When suppuration occurs the pain assumes a persistent throbbing nature, worse at night, until the pus makes its way through the periosteum of the bone, when the tension is lessened and the appearance of a swelling, usually in the sulcus between the gum and cheek, is often followed by a striking diminution of the pain.

Differential Diagnosis.

This should not be difficult, though in pulpitis the localisation of the tooth involved may not be easy. A few dental instruments, such as a mouth mirror, two or three dental probes, a pair of dental conveying forceps with curved ends, and a couple of excavators will be found useful. The history of the pain is important in differential diagnosis. Pain during eating, or when taking hot or cold fluids, or sweet substances, points to pulpitis. Paroxysmal pain is certainly due to an inflamed pulp. Dull and constant pain, unaffected by heat and cold, but made worse by pressure on the tooth, suggests periodontitis. In an obviously carious tooth superficial débris should be removed with an excavator. A probe should be used cautiously, lest the exposed pulp should be touched. Thermal tests should be applied: warmth by heating the handle end of a metal instrument, and placing the hot instrument on the dried crown. As for cold, if cotton-wool sprayed with ethyl chloride is exposed to a current of air it will freeze, and may then be applied to the tooth. Periodontitis is easily diagnosed by tapping the teeth with a metal instrument; this will at once reveal any tenderness. There is often an associated periodontitis in acute pulpitis, but it is slight and should not lead to confusion. Periodontitis tends to spread by continuity, so that more than one tooth may be tender, but the chief culprit will be looser and more tender than its neighbours. Digital exploration of the inner and outer gum side may reveal a tender or swollen area. Pain due to periodontitis is more localised than that caused by pulpitis, and referred pain is less common. The absence of a cavity in a suspected tooth should not preclude the diagnosis of periodontitis, for the pulp may have died as the result of a fall or blow. Such teeth are usually discoloured.

Treatment of Pulpitis.

If there is a large accessible cavity, the superficial débris should be removed with an excavator, the cavity should be dried, and a small pledget of wool dipped in pure phenol or oil of cloves is placed therein. A convenient preparation of phenol is carbolised resin. This consists of pure carbolic acid, 4 parts; resin, 4 parts; and chloroform, 3 parts. The mixture forms a viscid fluid. A small piece of wool should be dipped in this and placed in the tooth, and should be protected from the saliva by a watertight dressing. The use of gutta-percha is not advisable, except by an expert, for it must be used hot and packed in under pressure, and may thus increase the pain instead of relieving it. A convenient dressing is wool dipped in gum-mastic or gum-sandarac. This sets hard enough to last several days. In addition, the gum should be painted with tincture of iodine to aid in depleting the vessels of the pulp. Equal parts of the weak and strong tinctures of iodine form the best preparation. Counter-irritation is only an adjuvant in the treatment of pulpitis. Success cannot be guaranteed, but providing the inflammation has not gone on to the stage of suppuration and that the right tooth has been treated, the pain will in many cases be relieved for a few days. If these measures fail anodyne drugs may give relief; tr. gelsemium, 10-minim doses, may be combined with pot. brom., 10 gr. But drug treatment represents a less desirable and less certain means of relieving pain.

Treatment of Periodontitis.

In these cases the pulp is dead, and it is useless, and indeed harmful, to place a dressing in the cavity of the tooth. Any possibility of drainage through the pulp canal would thereby be made impossible. A piece of wool placed in the cavity during meal-times, and removed afterwards, is useful in preventing food from being jammed in the pulp canal. The only possible treatment is counter-irritation applied to the gum. Tincture of iodine, to which some tincture of aconite has been added, is the best drug. The gum should be dried and the excess of iodine squeezed out of the wool before applying. Penetration of the drug is increased if a current of warm air is directed on the gum. The strong tincture may be used, but should not be applied more than once. In subacute periodontitis counter-irritation is often efficacious, unless suppuration has supervened. A hot mouth-wash should be used frequently, the heat being more important than the ingredients, though weak carbolic is perhaps the best. A smart saline purge may help in the early stages. In severe periodontitis extraction is often the best treatment. Since such teeth are loose and their extraction may not be difficult, the medical practitioner need have the less hesitation in attempting their removal. A local anæsthetic should never be used in acute periodontitis, for the injection of fluid into the inflamed gum may result in severe after-pain and even necrosis.

L. E. Toney records[1] a case in which severe toothache was relieved by cocainisation of the sphenopalatine ganglion. A drop of saturated aqueous solution of cocaine was applied to the mucous membrane just posterior to the posterior tip of the middle turbinate bone. The pain ceased in five minutes. In obstinate cases of toothache, which cannot be relieved by other ways, this method might be worth a trial.

Treatment of After-Pain following Extraction.

The aid of the medical practitioner may be sought to relieve the pain following extraction of a tooth. If there has been laceration of the gum or splintering of bone the pain may be severe. The best way to relieve it is by irrigation of the socket. A syringe with a narrow nozzle and of about an ounce capacity should be used. The best lotion is carbolic, 1 in 100, as hot as the patient can tolerate. The socket should be gently flushed out several times, and the lotion used frequently as a mouth-wash. This will give great relief in a short time. If the pain is very acute, and there is a history of the tooth having been fractured, the pain is often due to the end of the pulp projecting from the broken root. Relief will be given by drying the socket and swabbing it out with pure phenol, or instilling powdered orthoform.

Conclusion.

It must be emphasised that the palliation of toothache cannot always be promised by measures short of those only available to the dentist. But the attempt to relieve pain is always worth making, and if a correct diagnosis has been made the attempt will often be successful.

A. T. PITTS, M.R.C.S., L.R.C.P., L.D.S.,
Dental Surgeon to the Hospital for Sick Children, Great Ormond-street; Assistant Dental Surgeon to the Royal Dental and Middlesex Hospitals.

Public Health Services.

A BRIEF HEALTH SURVEY.

DURING last year numbers of reports reached us, often containing in addition to the prescribed tables and summaries the considered views of men and women engaged in various branches of the public health service upon the material presented to them in 1922. We have already devoted considerable space to comments upon some of these reports—space precluded noticing every one—and it may be of interest to recapitulate here some of the more general lessons to be drawn from them.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

Statistics.—Apart from the epidemic of influenza during the first quarter, 1922 was a healthy year. The death-rate in most districts was a low one. The infant mortality-rate was frequently the lowest on record, although as usual the mortality among illegitimate infants was double that of legitimate. In many districts the tuberculosis rate, though low, showed a slight rise compared with 1921. The cancer rate in most districts was higher than that for all forms of tuberculosis. Many medical officers of health issued leaflets on cancer, the chief points emphasised being the avoidance of all forms of chronic irritation and the need for securing immediate medical advice on the appearance of well-recognised danger signals. The fatality of diseases of the respiratory system was largely increased by the influenza epidemic and a comparison of the fatality of these diseases in various districts showed a marked difference between town and country and between towns with clean air and those with dirty air. The reports have not indicated any serious desire on the part of the public to tackle the subject of smoke prevention.

Tuberculosis.—Many medical officers expressed dissatisfaction with the results of expenditure on tuberculosis schemes, and a considerable number stressed the importance of establishing complete convalescence after ailments of childhood and thus preventing the onset of active tuberculosis. A general complaint was that the disease is not notified at a sufficiently early stage. There appears to be a shortage of accommodation for advanced cases especially in counties, and a general shortage of accommodation for the so-called pre-tuberculous children and for children suffering from what is known as surgical tuberculosis.

Maternity and Child Welfare.—The need for more maternity homes appears to be general, and is rendered more urgent by the scarcity of houses. Many medical officers point to the necessity for more efficient antenatal work if the high maternal mortality and damage-rate from childbearing and the more or less stationary neonatal mortality are to be combated. The statistics show a great difference in the childbirth mortality in the various districts. For example, during 1922 the maternal mortality from childbirth in Glasgow was more than twice that of Liverpool or Birmingham. What has been the effect of the scarcity of houses on this mortality it would be difficult to say. Several schemes have been described in the reports under which the midwives are subsidised to carry out elementary antenatal work. More and more of the births are being attended by midwives.

Venereal Disease.—From most centres a decline in cases and an increase in attendances is reported. This is all to the good, but the reports show that a more determined effort is needed to secure control of the syphilitic expectant mother, and also the provision of immediate skilled treatment for cases of ophthalmia neonatorum.

Housing.—An almost general scarcity of houses is reported. Renovation of existing houses is thereby rendered impossible. Trade depression and high cost interfere with proper repairs. There is evidently much overcrowding. New municipal houses are frequently sublet in part because the rent is beyond the reach of the tenant's pocket. Several medical officers prophesy an increase in tuberculosis if an adequate solution of the housing problem is not found soon.

General Sanitation.—Owing to the need for economy, little is being spent on schemes of drainage and sewage disposal, water-supplies, conversion of privies, hospital and sanatorium extension, public abattoirs, and the like. There are many complaints with regard to refuse dumps, especially with regard to London refuse, but again the need for economy appears to stand in the way of an effective solution.

Administration.—Better coördination between child welfare and school medical departments has been frequently advocated in the reports. Closer coöperation between county councils and urban and district councils has been arranged, for example, in the case of Essex and Derbyshire. Large urban districts wish to have the control of the midwives brought into their maternity and child welfare schemes. The unvaccinated condition of the population has been a subject of frequent warning. There is a welcome tendency, in these days of motor ambulances, to reduce the number of white elephants by means of joint small-pox hospitals and to avoid the danger of missed cases of small-pox by utilising the services of expert diagnosticians. Such improvements in administration cost nothing.

Health Education.—Many medical officers lay great stress on the advantage to be expected from the better education of the public in hygiene, and more particularly in the right choice of food. It is unnecessary to labour the point that an educational policy of this kind is possible when other more ambitious schemes have to be postponed on account of financial stringency.

From the public health point of view it may be conceded that 1922 was a very difficult year owing to the prevalence of distress due to unemployment. Careful inquiries have been made in many districts, and there is some satisfaction in being able to record that owing to the coöperation of the various relief organisations little or no effect of the continued distress has shown itself either in the mortality-rates or in the state of nutrition of the school-children.

SCHOOL MEDICAL SERVICE.

A considerable number of school medical officers' reports have passed through our hands during the year, and, much as we have been impressed by the high standard of attainment in face of formidable difficulties, practical as well as economic, the real sincerity of effort presented in these reports has impressed us even more. The aim of the school medical service is dissemination of health by prevention of disease in the young, and encouragement of a health conscience amongst the population generally. A health conscience is by no means synonymous with the health consciousness, rapidly being fostered in American schools by means of instruction and literature, which, if not checked, is likely to have a disastrous psychological effect sooner or later. In this country the school doctor is now an institution firmly established in the general routine. His removal would be a national calamity. The children of those who passed through his hands 15 years ago when medical inspection of schools became statutory are making his acquaintance to-day. In many areas treatment for defects follows closely on the heels of inspection, and it would not be unsafe to predict that in ten years time this will be the natural order throughout the country. Special schools of every kind, these reports show, have materialised, and are materialising through the efforts of the school doctor in spite of financial stringency.

We cannot help being struck, however, on reviewing the reports, by the profound apathy of public opinion on the general conditions prevailing in the majority of elementary schools. Last year school medical officers'

reports on school buildings revealed a standard of general hygiene alarmingly low. This year we find very little record of improvement in this direction. The amenities of life in our elementary schools should surely approach as far as possible those of the ordinary middle-class household. How far they fall short of this is known to every school doctor. Children, perhaps more especially in country districts, leave school at 4 P.M. in the wet clothes and sodden boots they sat down in at 9 A.M. In such manner are laid the foundations of disease—tuberculosis, rheumatism, chorea. It ought to be possible—indeed, a few schools find it perfectly simple—for children to make in class cheap warm slippers and woollen stockings into which to change on entering school; and to devise some means of drying clothes and boots, even in the depths of the country, ought not to be past the wit of man. Then again there are schools where wash-hand basins, but neither soap nor towels, are provided; there are others with wash-hand basins but no water; in some for a hundred children the provision is a single towel, changed weekly. In not one school in a dozen are children's closets supplied with toilet paper; indeed, one school doctor reported that conditions in this direction were worse than in the front-line trenches. Many schools in this country have no drinking water, many provide one drinking cup for the whole school, others one for each department. The continental system of releasing a jet of water into the mouth by pressing a button has hardly reached us yet. In the matter of floor space, too, England has, of all the world, the smallest national requirement. It has not been changed since the Education Act of 1870.

These points are brought forward in no carping spirit. The school medical service has done more in a few years to raise the health standard throughout the country than was ever contemplated. It has demonstrated, too, by careful research on growth, malnutrition, and mental retardation, amongst other things, the important rôle played by environment in the moulding of character. Although by no means the major part of the child's life is spent in school, it is to the school he looks for guidance, and habits formed there go far to making the man. Theoretical teaching of hygiene without practical application is wasted time and effort. A higher minimum requirement of everyday hygiene should be laid down for the public elementary schools; and while recognising how difficult a task awaits the reformer in this direction, we would, in all seriousness, recommend its urgency to the school medical service, which alone can educate public opinion on such a question.

Mental Hospitals Service.

Improvements in this service are to be observed in many cases. There has been a notable increase in the provision of out-patient treatment for incipient cases. Buildings which had fallen into dilapidation during the war years have been repaired or reconstructed, better diet is reflected in a reduced incidence of tuberculosis, staffs have been increased, and more specialised work is being undertaken, some pathological, psychotherapeutic, and medicinal, by resident staffs, and some, such as dental and surgical, by recently appointed visiting officers. There are, however, institutions in which some of these changes have yet to be made. There are many more in which formidable barriers stand in the way of changes which are deemed necessary for the welfare of their inmates. The buildings themselves are ugly without and within, badly arranged, inadequately lighted and heated. No separate accommodation exists for recent admissions or for cases of open tuberculosis. The airing grounds are small, and the washing, sanitary, and general domestic accommodation antiquated. Laboratories, therapeutic baths, operating theatres, X ray equipment, and private rooms for interviews and psychotherapy are non-existent. Medical officers are often inadequately paid, and entry into the service is discouraged by the fact that married quarters are often available only for superintendents. Promotion is slow, and dependent rather on business and organising ability than on professional attainments. Women whose character and education fit them for the work of a mental nurse cannot be persuaded to enter the nursing service in sufficient numbers, and an unduly large proportion of nurses, both male and female, never obtain their certificate. Provision for "after-care," where it exists, is patchy and incoördinated, and money allowances are often not available for patients on leave of absence.

Not the least anomalous feature of the present service is its gross inequality. Whereas the native of Cardiff, Birmingham, or Edinburgh is received into a modern or modernised hospital, excellently staffed and equipped, the pride and concern of every intelligent ratepayer in the city, the insane poor of many districts must be relegated to institutions labouring under the depressing handicaps outlined above, the work and needs of which are practically unknown to the vast majority of those who, as local government electors, are responsible for their welfare. Too much is being sacrificed to economy, and as the law stands no one can interfere. Visiting commissioners "recommend," and occasionally "protest," as at the flagrant example of Carnarvon, where the medical staff has been reduced deliberately from three to two members, but their biennial recommendations are repeated so interminably, so plaintively, and with so little effect, as to become ridiculous and even pathetic.

It would be unwise to rely on the likelihood of convincing each individual local authority of the need for heavier expenditure on the insane. But there is another reason for the need of some sort of unified control, for only under such control could the existing and projected resources of the service be used to the best advantage. When such an authority comes into existence, it will destroy some of the oldest and most dreary asylums, utilise the remainder of this class for the housing of the incurably insane, and build new and genuine "mental hospitals," properly staffed and equipped, for the reception of recent, and the treatment of recoverable, cases. Although there is no immediate prospect of any changes on this scale the volume of more or less enlightened public opinion from which they must ultimately result has certainly increased during the last few years.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdrs. A. R. H. Skey, R. H. Mornement, J. H. Fergusson, H. C. Whiteside, and J. R. Muir to be Surg.-Capts.

Surg. Comdr. C. J. E. Cock is placed on the ret. list with the rank of Surg. Capt.

Surg. Lt. G. D. G. Fergusson to be Surg. Lt.-Comdr.

ROYAL ARMY MEDICAL CORPS.

MILITIA.

Maj. W. R. Gardner relinquishes his commn. and is granted the rank of Lt.-Col.

TERRITORIAL ARMY.

Capt. W. Baxter (late R.A.M.C.) to be Capt.

TERRITORIAL ARMY RESERVE.

Capt. D. H. Scott, from General List, to be Maj.

ROYAL AIR FORCE.

Flying Officer G. Kinneir is promoted to the rank of Flight Lt.

INDIAN MEDICAL SERVICE.

The King has approved the retirement of Lt.-Cols. J. Entrican and D. MacD. Davidson.

Shiv Das Suri, Shambhoo Dayal Misra, Subbier Annaswami, and Amar Nath Duggal to be temp. Lts.

Special Articles.

SURGICAL TUBERCULOSIS IN ADULTS: THE WORK OF THE M.A.B.*

ST. LUKE'S HOSPITAL, LOWESTOFT.

VISITORS to Lowestoft will doubtless remember the magnificent Empire Hotel which was built on the front about a score of years ago. The promoters of this palatial building grudged no expense, and they anticipated that it would prove an attractive and fashionable centre. It was not, however, a great success, and when the war came, the hotel was occupied by soldiers, and its parquet floors supported a machine gun instead of dancers. For some time after the war the hotel stood as an empty neglected shell—a white elephant embarrassing its owners. At this stage the Metropolitan Asylums Board stepped in and careful inquiries were made as to the suitability of this building for a hospital for surgical tuberculosis. This proving to be the case, the purchase was completed and the hotel with its beautiful oak and mahogany panelling, stained glass windows, lofty billiard room, library and reception rooms came into the possession of the M.A.B. Many alterations had, of course, to be made. The central heating system was very imperfect and had to be entirely reconstructed. Even the kitchens required a certain amount of re-modelling; a grill, for example, may be essential to an epicure, but is out of place in a hospital. The six storeys are connected by four lifts, only two of which carry human beings. The hospital provides its own electricity, it has an up-to-date X ray outfit, a 12-inch coil (100 volts), a Coolidge tube, &c.

St. Luke's Hospital for Surgical Tuberculosis at Lowestoft.

Scope of the Hospital Work.

The hospital takes only cases of surgical tuberculosis in adults—i.e., patients over the age of 16. It is the only institution of its kind under the M.A.B. and it fills an important gap in the tuberculosis scheme of this organisation. Before St. Luke's Hospital was opened on May 9th, 1922, the M.A.B. possessed no special institution to which it could admit adult cases of surgical tuberculosis, although in Queen Mary's Hospital at Carshalton and Princess Mary's Hospital at Margate it had for some years past maintained several hundred beds for juvenile patients of this type. St. Luke's is open to L.C.C. patients, and about 99 per cent. of the patients hitherto admitted are Londoners. It is inevitable that a first-class institution like this must attract the attention of the health authorities in the neighbourhood, but the needs of the L.C.C. have, of course, to be satisfied first. Nevertheless, if an arrangement for the admission of local cases could be made, it is one which might well be profitable to all parties. The hospital has facilities for expanding its present accommodation, and the cost of running a few dozen more beds would be considerably less in this institution than in an independent concern requiring a new central organisation.

The female staff numbers 66, including 37 nurses. The male staff numbers 27 and lives outside the institution, while the female staff sleep in. The doctors are resident. At present the medical superintendent has only one assistant, but a third medical officer is shortly to be appointed. The wards vary greatly in size; the largest female ward has 25 beds. On the first floor two or more rooms have been thrown into one, while others retain their original size. The wide range of choice between large, medium-sized, and small wards has enabled the staff to distribute the patients to a certain extent according to their instincts—the gregarious instinct or its opposite. What this means to the comfort of the patients, only those can tell who have had experience of running a large institution like this.

Accommodation.

At present there is accommodation for 94 male and 70 female patients. There is no arbitrary limit to the duration of residence, the average being from six to eight months for patients with tuberculosis of the bones. This average is only four to five months for patients suffering from tuberculous adenitis or peritonitis, and the patients who come for observation and diagnosis sometimes only stay a few weeks. Pulmonary tuberculosis does not, of course, qualify a patient for admission, but in a small proportion of cases it is found as a complication of surgical tuberculosis. It must, by the way, be sometimes rather

* An article on Surgical Tuberculosis in Children: the Work of the M.A.B. appeared in THE LANCET of Sept. 23rd, 1922 (p. 683), and one on Pulmonary Tubercle in Adult Males in THE LANCET of Dec. 2nd, 1922 (p. 1189). All three articles are the outcome of visits by our own Commissioner).

difficult to say when surgical tuberculosis is complicated by pulmonary tuberculosis, and when the reverse is the case. At first a relatively high proportion of the total were gland cases, an accumulation of which had occurred before the hospital was opened. But it is anticipated that the proportion of spine and joint cases will increase as time goes on. During the last 12 months the hospital discharged the following cases: Spines, 63; hips, 43; knees, 25; other joints and bones, 30; abdomen, 16; peripheral glands, 28; genito-urinary system, skin, &c., 14.

Factors in the Treatment.

Dr. W. M. Oakden, the medical superintendent, considers rest by far the most important remedy in the acute phase of surgical tuberculosis. About two-thirds of the patients are confined to bed, the numerous verandahs of the hospital providing plenty of fresh air and some of the sunlight which struggles out even in winter, and in the British Isles. Heliotherapy and radiotherapy are not practised with the fervour shown in some of the continental hospitals for surgical tuberculosis, and tuberculin (B.E.) is given only in selected cases, the results being sometimes good and sometimes indifferent. But rest by immobilisation is a fine art at St. Luke's, and the spinal frame, devised by Dr. Pugh for juvenile cases, and slightly modified by Dr. Oakden for use with adults, is a remarkably ingenious contrivance on which the patient can be left for a month without disturbance and without fear of bedsores and other calamities. It is suitable with slight modifications for hip as well as for spine cases, and among its many merits are its non-retention of crumbs, sweets, and the like, so productive of sore backs, and the facility with which it allows the use of the bed-pan. Abscesses that do not subside with immobilisation are aspirated, while sinuses are injected with bismuth-iodoform paste after the removal of existing sequestra by operation. It is not the practice to leave sequestra to the expulsive and curative action of heliotherapy alone. The treatment of lupus consists in scraping and cauterising with such agents as carbolic acid, acid nitrate of mercury, or fuming nitric acid. The metal of which spinal braces and other splints are made is "duralumin," which is remarkably light and strong.

Plaster immobilisation is also practised, but the celluloid jacket or splint is not favoured for various reasons, such as the lengthy process of production, the cramping of certain necessary movements which it entails, and the sometimes undesirable warmth it gives. The hospital is equipped with a well-stocked dispensary, but it is seldom found necessary to give patients drugs. The diet is ample, plain, and nutritious; there are four meals a day, and snacks between meals as well as stuffing patients with extra eggs, and that sloppy nutriment known as milk, are not encouraged. The operating theatre is well equipped, 100 candle-power lamps being placed so as to give the operator excellent illumination. It is, however, seldom necessary to operate on cases coming under treatment at an early stage. Excision of a knee or other joint is performed where ankylosis is a moral certainty and time can therefore be gained in the period of treatment. It is the opinion of Dr. Oakden that in some cases early operation defeats its object, better results being obtained by waiting until the general condition of the patient has improved by some weeks' residence in hospital away from London. Bier's treatment by passive congestion is not practised at St. Luke's. It is perhaps inevitable that some of the cases sent to St. Luke's with the diagnosis of tuberculous cervical adenitis should be found to have carious teeth, and in this connexion it should be noted that a Lowestoft dental surgeon attends regularly.

Psychic Factor.

There is much to be said in favour of a hospital which is not built as such, but is adapted from a private mansion or hotel. Beautifully carved oak and mahogany may doubtless be accused of harbouring dust and germs, but at least it does not harbour that chilling spirit that lurks in the bevellings of the sanitary architect. In a chronic disease like tuberculosis the psychic factor is most important, and the patient who enters St. Luke's is persuaded by his surroundings to feel himself the inmate of a first-class hotel and not of an isolation hospital. And were not the subjects of tuberculosis promised first-class hotel accommodation when the Insurance Act was born? St. Luke's Hospital is proof positive that politicians are sometimes able to carry out their intentions.

BUDAPEST.

(FROM OUR OWN CORRESPONDENT.)

The Increased Mortality-rate in Hungary.

THE Central Statistical Bureau of Hungary has just published the figures relating to the rate of population in the year 1922. The importance of these figures lies in the fact that they reflect the situation prevalent in the country for the last three years; the consequences of a lost war and the unblessed litigations following it. The births are seemingly at a standstill, whereas the mortality-rate has increased over the already large figure for the previous year. Amelioration of this state of affairs is the urgent duty of the Supreme Sanitary Council. The Council does not attribute the unfavourable death-rate to bad hygienic conditions, but rather to the adverse economical position of the land. The total number of marriages in 1922 was 83,372—that is, 4717 less than in the previous year. There were born 220,898 living children against 211,697 of the preceding year, an increase of 1·2 per 1000 of the population, but the number of births is not at all satisfactory. The slight rise is destroyed by the higher death-rate. In the year 1921 there were 146,485 deaths, while in 1922 there were 154,857. The ratio per 1000 rose from 18 to 19·6. The number of deaths due to infectious diseases is remarkable. Tuberculosis claimed first place with 19,057 cases, the mortality-rate being 2·41. Measles and scarlet fever caused the death of 6225 children compared with 2620 in 1921. The infant mortality-rate is still on the increase; in 1922 it was 195 per 1000 live births. The increase of population arising out of the difference of births and deaths amounted in 1922 to 69,743, or 8·5 per 1000 inhabitants; this corresponds to an improvement of 0·2 per 1000 in comparison with the previous year. During last year there were 1469 emigrants, mainly to the United States of America, while immigrants numbered 1802.

A New Factor in the Ætiology of Ectopic Gestation.

Dr. Alexander Gross writes in the *Orvosok Lapja* that the evident widespread avoidance of pregnancy in married women may be attributed with some justice to the economical crisis following the war, and the severity of the struggle for life. It was formerly a common occurrence for wives with large families to seek the advice of doctors regarding the different contraceptive methods and drugs, but it now often happens that young engaged girls come to doctors for advice how to be childproof in their ensuing marriage. At present one of the contraceptive methods in vogue is the intra-uterine injection of iodine. The wives are "demanding" this, says Dr. Gross, if their menstrual period is even a few days overdue. This procedure may be injurious. Laszló, a Hungarian, has called attention to the fact that iodine injections occupy an important place in the ætiology of ectopic gestation. Who can tell the position of the fecundated ovum—if it is fecundated at all—at this stage of development? A prophylactic iodine injection may cause the ovum to adhere at an irregular situation and thus bring about a dangerous condition. Dr. Gross explains this as follows: (*a*) The effect of the iodine is to produce inflammation and thickening of the mucous membrane of the uterus and consequently of the ostium uterinum of the Fallopian tube, which is normally of 1 mm. diameter.

The ostium contracts, and thus the ovum, which is of 1 mm. diameter when it reaches the ostium, cannot get into the uterine cavity, and is obliged to settle in the tube. (*b*) With the iodine injections a part of the iodine gets into the tube and causes an endosalpingitis catarrhalis, and this, according to Fränkel, stays the migration of the ovum without retarding its development, thereby favouring the embedding of the ovum in the tube. He quotes several cases of his own, in which the occurrence of ectopic gestation could be brought in ætiological connexion with intra-uterine iodine injections. Moreover, the presence of iodine in the tube can give rise to serious abdominal consequences.

New Order of Examinations in the Medical Faculty.

The official journal of Hungary contains the order relating to the alterations in the scheme of the examinations to be passed by medical students. In order to get a medical diploma the candidate will have to pass four examinations instead of three, as at present, and as the first examination will be divided into two halves there will be, in effect, five examinations necessary. One-half of the first examination (physics and chemistry) must be passed at the end of the second session; the second half (anatomy and physiology) at the end of the fourth session. A candidate who fails in the first part may sit again in the first month of the third session; if failing again, then at the end of the fourth session. Re-entry for the second part of the examination is allowed only at the beginning of the fifth session. The second examination must be taken as hitherto at the end of the tenth session—that is, if the student has received the absolutorium (a certificate of having attended all subjects for the prescribed period of at least ten sessions). This examination, written and oral, will be easier than previously, as it will consist of general pathology, pharmacology, and pathological anatomy only. In the third, or final, examination the order of subjects has not been altered. There are two parts: the first embraces all practical work and the second consists of forensic medicine and public hygiene. The new regulations embody several useful innovations, and the division of the examinations makes them less of a strain. On the other hand, by spacing the intervals between the examinations the period of study has been extended by one full year.

BOGUS MEDICINE IN THE UNITED STATES:

THE VALUE OF HONEST JOURNALISM.

(FROM AN OCCASIONAL CORRESPONDENT.)

IT has been publicly stated that no less than six medical boards grant licences to practise medicine in the State of Connecticut.[1] One of these boards is composed of eclectic doctors who are authorised to give diplomas to those who wish to practise along these lines. Last summer the State Commissioner of Health began to investigate some of the licences granted by this board with the result that 53 of them were withdrawn. The State legislature thereupon passed a Bill to make the licences valid again, but the Bill was vetoed by the Governor of the State. The movement for reform, started by the *New York Evening Post*, I believe, seemed to be leading nowhere. There the matter might have rested but for the enterprise of a reporter on the St. Louis *Star* in Missouri. This gentleman was supplied with money by his enterprising journal, and by the judicious use of $3000, and after 2 hours and 22 minutes of intensive study, he was soon able to report that he had obtained (1) a certificate stating that he had completed his high school course in Missouri, (2) a document granting him the degree M.D. of a university that has been extinct for five years, (3) a diploma attesting the degree of doctor of chiropractic, and (4) a licence to practise medicine in Tennessee. The ingenious and humorous journalist thus let in a flood of light upon the secret organisation of the diploma manufactures of the United States.

Briefly, the procedure was to forge a diploma from some third-rate medical college in the State wherein their customer desired to practise. If it were the diploma of some college, which through the educational propaganda of the A.M.A. had been obliged to close down, that was so much the better. In the event that no such college existed in the desired State, then a licence to practise in some other State must be obtained whence by reciprocity the same end could be achieved. Thus it came about that Arkansas and Connecticut were particularly useful. In Connecticut it was necessary for the applicant to pass the State examinations. Sometimes this was arranged by proxy, at other times an examiner could be induced to pass out the questions beforehand, and the little group of aspiring "physicians" would spend an evening memorising the correct answers.

The immediate effect of this exposé has been the reviewing of licences. Eighteen eclectic doctors, in addition to those already deprived of their deceitful status, and some of them had been practising as long as nine years, have now lost their licences in Connecticut. Missouri has decided to review the licences of the 6000 physicians practising in that State, and in New York city a survey is being made of the educational history of all hospital internes. But the final results are likely to be still more important, for the wide publicity given to this scandal by the lay press has aroused public opinion all over the country. The *Survey* (Dec. 15th, 1923) forecasts a special session of the Connecticut legislature to revise the Medical Practice Act. If this revision is brought about, as it almost certainly will be, and certain other States also fall into line, a very valuable advance in American medical standards will be accomplished.

I know that the existence of this scandal has for years been perfectly familiar to your readers, but the array of sound journalistic opinion on the side of right bids fair to introduce reform.

[1] Laws and Board Rulings, published by the A.M.A. and revised to July, 1923, lists three boards—viz., regular, homœopathic, and eclectic.

SOUTH AFRICA.

(FROM A CORRESPONDENT.)

The Responsibility for a Swab Left in a Patient.

JUDGMENT was given recently at the Queenstown Circuit Court, Cape Province, by Mr. Justice van der Riet, in a case in which the plaintiff, Gwendoline van Wyk, sought to recover the sum of £2000 from Dr. Harry Lewis, of Queenstown, for alleged negligence in leaving a swab in her abdomen after an operation. She sued in forma pauperis, and was represented by Mr. Advocate Pienaar, of the Capetown Bar. Mr. Advocate Lewis, K.C., and Mr. F. B. van der Riet appeared for Dr. Lewis. The plaintiff alleged in her declaration that at Queenstown Hospital, on Feb. 3rd, the defendant operated upon her; that he carelessly and negligently left a swab within her body; that on divers occasions subsequently he examined her, but failed to detect and remove the swab; that it remained till Feb. 15th; and that, owing to its presence, she had suffered great bodily pain and anxiety, and had been put to considerable expense. Mr. Justice van der Riet gave judgment for the defendant. He found that, although the swab was left in the body, Dr. Lewis was not guilty of any negligence, and that he was entitled to relegate the duty of checking the number of swabs to the theatre sister.

Transvaal: Resignation of Dr. C. L. Leipoldt.

The Transvaal has suffered a serious loss by the resignation of Dr. C. L. Leipoldt, medical inspector of schools for the province. Dr. Leipoldt's resignation for private reasons was not unexpected, but it will be difficult to replace him. He was formerly an assistant

medical officer under the London County Council, which he left to become the pioneer of school hygiene in South Africa. He organised here a scheme of medical inspection and treatment which has served not only for the Transvaal, but as a model for South Africa as a whole, and his work on hookworm disease is now a classic. Dr. Leipoldt's energy and enthusiasm in any work he undertakes are boundless, and doubtless more will be heard of him.

The department has sustained a severe loss, too, in the death of Dr. Anne F. Cleaver, little more than a year ago. Dr. Leipoldt puts on record in his last report his appreciation of the good work she accomplished. A representative committee has been formed for the purpose of perpetuating her memory by the establishment of a university scholarship to be called the Anne Cleaver Memorial Scholarship, and by the erection of a mural tablet in the Johannesburg School Clinic, "where she worked so effectively, and which she was largely instrumental in establishing."

Medical Council Conference at Johannesburg.

A South African Medical Council Conference, dealing with the uniform training of nurses and midwives in the Union, was opened at Johannesburg on Dec. 3rd, 1923. The Cape Medical Council was represented by Drs. Darley-Hartley, F. C. Willmot, and Barnard Fuller; the Free State by Dr. G. D. de Kock; Natal by Dr. W. Russell Strapp; and the Transvaal by Drs. W. T. F. Davies, J. van Niekerk, A. H. Watt, and R. P. Mackenzie. The South African Nurses' Association was represented by Dr. John Tremble and Miss B. G. Alexander, general secretary, who acted as delegates in an advisory capacity.

A Medical School for South African Natives.

A proposal has been formulated for the institution in the near future of a medical school for native students at Fort Hare. The idea is that preliminary education in the fundamental sciences will be given for two years, to be followed by a three years' course in clinical work in the Durban coloured hospital.

IRELAND.

(From our own Correspondents.)

An Inquiry into the Medical Services in the Free State.

It is announced that the Minister of Finance has decided to appoint, in the present year, a committee of inquiry into the working of the Health Insurance Acts in the Free State, and that such inquiry will include the question of the medical services generally, as well as in their relation to the medical treatment of the insured people and their dependents. Such a step has been urgently needed since the establishment of the Free State Government. In 1920 the Irish Public Health Council drew up a radical scheme of reform for the medical services of the country, including the provision for the treatment of the insured. No action was taken on it by the then Government, but the first Dail, and more recently the Free State Government have encouraged some of the changes recommended by the Irish Public Health Council, but the changes have been adopted in a piecemeal fashion. It is difficult to say whether more confusion than order has not resulted from these reforms. It is to be hoped that the committee of inquiry will be a representative and capable body in which the profession and the public can have confidence, and that it will tackle its work with courage.

National Health Certification.

The Irish Medical Committee was warned a few weeks ago by the National Health Insurance Commission that, the Government having declined to make any further grant for certification purposes after the end of 1923, it would be impossible to provide remuneration on the same scale as hitherto. The Chairman of the Commission has now submitted to the Irish Medical Committee a memorandum, in which he sketches the history of the special grant, and outlines the proposals of the Commission for the future. He states that, in 1915, after a prolonged controversy, the British Treasury agreed to make a grant not exceeding 2*s*. 6*d*. per insured member for the purpose of defraying the cost of certification in Ireland. The maximum grant for any area was limited to 2*s*. 6*d*., and a scheme was prepared which provided for three rates of capitation, varying from 2*s*. 6*d*. in the most scattered rural areas to 1*s*. 3*d*. in urban areas. These rates came into operation in the beginning of 1916, and continued until Jan. 1st, 1920, when an increase of 40 per cent. was approved owing to the increased cost of living. In 1922 half of the increase was taken off, and since January, 1922, the capitation rate has stood at 20 per cent. over the original figures. Early in 1922, with the disappearance of the Treasury grant in Great Britain, the special grant in the Free State would also naturally have disappeared. The Insurance Commission, however, felt that a very serious position would arise if the cost of certification was placed on the funds of approved societies, owing to the fact that political troubles had caused a considerable amount of non-compliance as regards stamping. The Commissioners approached the Government, and, as a result of their representations, the grant was continued for the years 1922 and 1923.

The Proposed Capitation Fee for 1924.

The assent of the Government was given on the condition that no further grant would be asked for, and that before the end of 1923 arrangements would be made to provide the cost of certification otherwise than by a State grant. In these circumstances the Commission took the advice of the Chief Government Actuary as to how far it would be safe to draw on the benefit funds of the societies. In his report, which is quoted by the Commission, the actuary states definitely that the benefit funds could not safely be touched at all for this purpose, and he gives his reasons why the problem in Ireland differs from that of Great Britain. He suggests, however, certain other subsidiary funds from which some monies could be taken. In addition to the sources suggested by the actuary, the Commission is willing to ask for legislative authority to transfer other monies temporarily at their disposal, which would make up in all a sum equal to the product of a rate of 2*s*. on the average per insured person, and which would be devoted to the cost of certification in the Free State. The net proposal, as far as the medical profession is concerned, is that the profession is asked to accept a reduction of 3*d*. in the average capitation rate, it being proposed at the same time to take 5*d*. off the administration expenses of the societies. The proposal is confined to the year 1924, and the Commission hopes that the profession will accept the offer now put forward, and prevent a deadlock arising as to the provision of certification for the current year.

The late Sir John Walton Browne.

The death of Sir J. Walton Browne, which was announced in your last issue, has caused very deep regret to a wide circle of friends in Belfast, both among the medical profession and the general public. Sir Walton Browne filled many posts of honour in the gift of his professional brethren. In 1913 the honour of Deputy Lieutenant was conferred upon him by Lord Pirrie, K.P., and when in 1921 he received his knighthood, it was felt by all his many friends as a well-merited recognition of his services. He enjoyed great popularity among his medical brethren in Belfast, to whom his genial and kindly character, which was not obscured by an occasional brusqueness of manner, endeared him in a high degree. No less high was his repute as a surgeon, especially in the branch of ophthalmic surgery. He had the gift of friendship, and was never more at home than at the social board, public and private. His presence radiated good fellowship and hearty enjoyment. He was also much beloved by his patients, and by his subordinates in the various hospitals with which he was connected.

Sir Walton Browne was twice married. By his first wife he had a son, the late Dr. James Browne, who died some years ago. By his second wife, who died two years ago, he had a daughter who is now the wife of Colonel Young. The funeral took place on Dec. 22nd, when the large and representative gathering bore witness to the esteem in which he was held.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

The Glasgow Western Infirmary.

THE annual Christmas meeting of the infirmary was held in the Dispensary Hall on Dec. 24th last. Colonel J. A. Roxburgh, the chairman of directors, in outlining the work of the past year, said that every bed had been occupied for practically the whole period, nor was the waiting list reduced. He referred to the absence from teaching work of Sir William Macewen, now in Australia, and of Sir Kennedy Dalziel, incapacitated by illness. The training of nurses under Miss Gregory Smith had been further facilitated by the addition of a lecture-room and a study-room, and the number of pupils in the massage department had been maintained. Reference was also made to the use of insulin in the medical wards, and it was pointed out that these patients were more costly to maintain than the average. It had been possible to reduce the ordinary expenditure for the year by about £3000, but there had been a falling off in the amount of subscriptions, partly as a result of unemployment, so that the deficit for the present year would not be less than for the preceding one (£13,000). During the year the endowment fund had been increased by £22,500, and there were now 82 beds permanently endowed in the infirmary. The legacy received last year from the trustees of the late Mr. Alex. Elder had been used for an extension to the nurses' home, now nearly completed, a nurses' study and lecture-room, now completed, and a memorial chapel to Mr. Elder, which would be finished next year. Colonel Roxburgh also referred to the experiment which is now being tried in the McAlpine Nursing Home, Glasgow, of offering accommodation at reduced rates to those whose income is limited, and hoped that this innovation would lessen the long waiting list of the infirmary. On the other hand, subscriptions to the infirmary from this type of patient had last year totalled £1722. Lady Blythswood then presented the nursing prizes gained during the year. During the meeting Colonel D. J. Mackintosh, the medical superintendent, was informed that another bed had been endowed in the hospital.

Medical Demonstrations for Practitioners.

The Glasgow North-Eastern Division of the British Medical Association have arranged a short series of demonstrations during the present winter to which all the medical practitioners in the area are invited. The first of the series was held on Dec. 12th, when a demonstration was given in the orthopædic department of the Western Infirmary, Glasgow. After a brief statement on the work of the department and on the course of training received by the students of massage, practical illustrations were given of the various methods of treatment, including massage, medical gymnastics, and electrical treatment. A number of patients were shown illustrating the types of cases suitable for the various forms of treatment. About 50 members were present, and the demonstration was much enjoyed.

Hospital Extension.

At a meeting of the Campbell Hospital Board at Portsoy, Banffshire, on Dec. 27th, the question of providing an observation ward at the hospital was discussed. A proposal for a discharging ward was also brought forward. Although the hospital provided ample accommodation for zymotic diseases arising in the neighbouring districts, many cases were admitted where an immediate diagnosis was quite impossible; such cases required investigation, and should be kept in an observation ward until an accurate diagnosis could be made. As regards a discharging ward, it was noted that certain cases of scarlet fever took a considerable time before they were free from infection. The board decided to adopt the principle of observation and discharging wards, and agreed to engage Mr. McCallum, architect, of Cullen, to prepare plans and estimates for the new wards and to report to a special meeting of the board.

At a meeting of the Kingseat Mental Hospital, Aberdeenshire, on Dec. 27th, a communication was submitted from the General Board of Control, Edinburgh, approving of the proposed extension of the hospital. It was agreed to instruct the architect to prepare plans and estimates for two new villas and also an addition to the nurses' home.

Correspondence.

"Audi alteram partem."

ON SOME USES OF DIGITALIS.

To the Editor of THE LANCET.

SIR,—On the above subject (THE LANCET, Dec. 22nd, 1923, p. 1376) Dr. Harrington Sainsbury's confession of faith may be summed up as follows: "I believe in drugs which will act directly and beneficially on the cardiac power of contraction." He is prepared with reasons for his faith, but has not grasped quite clearly all that is conveyed by his dogma. Pharmacologists teach that the action of digitalis on the heart is twofold, being indirect through the medium of nerves (the vagus), and direct through its action on the contractile tissues. Clinicians, on the other hand, while recognising the therapeutic effect of digitalis through the nervous system, are divided in opinion as to the existence of any direct and beneficial action on the contractile tissues of the heart. All are agreed as to the indirect influence of digitalis on the heart through the nervous system, and the only point of difference is as to the direct and beneficial action of digitalis—or any other so-called heart stimulant—on the cardiac contractile tissues.

In giving reasons for his belief, Dr. Sainsbury deals first of all with physiological conditions under which the heart is constantly receiving through the nervous system stimuli from all parts of the body, which regulate its action. He describes these stimuli as "influencing directly the muscle fibres of the heart." Yet by his own showing the action is indirect and not direct, for the stimuli act through the nervous system and not directly on the heart. He next instances the case of a fainting subject revived by the application of strong ammonia to his nostrils. Here he says "the powerful stimulus of the ammonia has been projected from the mucous membrane of the nasal cavities, via the central nervous system, upon the heart." This is another example of reflex and not of direct action on the heart. Supposing the reviving patient uttered a cry, would Dr. Sainsbury say that therefore ammonia had a direct effect on the muscles of the vocal cords? Possibly the patient might use a swear word. Would Dr. Sainsbury then say that ammonia was a direct stimulant of bad language or the centre regulating such?

Leaving his clinical studies, Dr. Sainsbury next descends to the pharmacological laboratory for further proofs. Now let us grant him all the laboratory proof he wants. Let us grant that in laboratory experiments on the hearts of healthy animals, perfused or otherwise, digitalis has been shown to have a direct action on cardiac muscle, making it contract more and more firmly, until it finally stops in a state of tonic contraction—poisoned by digitalis. Were Dr. Sainsbury a pharmacologist only no harm would be done, but he is also a distinguished physician,

and the saddening thing is to see a clinician accepting the results of laboratory experiments as applicable to the treatment of diseased persons, without any attempt to test them carefully at the bedside. The assumption that laboratory experiments with drugs are sufficient to settle the question of their action and suitability in diseased conditions has probably led to more therapeutic failures than any other fallacy in medicine. No laboratory experiments could ever have taught us the action of digitalis in auricular fibrillation resulting from heart disease, because the same conditions do not exist in animals experimented on. To prevent misunderstanding, let me add that no one appreciates the value of pharmacological work in the laboratory more than myself.

Dr. Sainsbury completes his evidence by a reference to a recent paper by Dr. Bodon, of Budapest, on the Intracardiac Injection of Adrenalin. Dr. Bodon has had one case thus treated, but in foreign literature he finds references to 90 other cases. Prof. Velden has treated half of these—45 in all—and none of his patients lived more than eight hours after the injection. Whether this settles the question of direct action on the heart muscle or not must be left to Dr. Sainsbury, but the second part of his dogma—the beneficial action on the heart—is not left in much doubt.

Dr. Sainsbury is more provocative when he accuses the present writer of not having done justice to the facts of the case, or to the memory of past observers. He seems hurt that no reference was made to the knowledge of the type of case suitable for digitalis possessed by our teachers of 40 to 50 years ago. Why, Sir, it was known 150 years ago! Dr. William Withering, the father of digitalis therapy, wrote in 1785 as follows: "If the pulse be feeble or intermitting, the countenance pale, the lips livid, the skin cold, the swollen belly soft and fluctuating, or the anasarcous limbs readily pitting under the pressure of the finger, we may expect the diuretic effects (of digitalis) to follow in a kindly manner." Whether we call it 50 years or 150 years Dr. Sainsbury can see no sign of progress. Of this I am certain, that were Dr. Withering alive to-day he would acknowledge and welcome, as I do, the great advances in our knowledge of digitalis therapy made by Sir James Mackenzie and his co-workers. It is no injustice to the past to lay stress at times on the advances of the present. We are not a boasting nation, but English medicine is entitled to claim that Sir James Mackenzie has taught us something that was not known 40 to 50 years ago, else his name had not been honoured and his writings had not been studied in every part of the civilised world as they are.

I am, Sir, yours faithfully,

G. A. SUTHERLAND.

Wimpole-street, W., Dec. 24th, 1923.

OPIUM IN CARDIAC DYSPNŒA.

To the Editor of THE LANCET.

SIR,—I much regret if I have done an injustice to Sir Clifford Allbutt (THE LANCET, Dec. 29th, 1923, p. 1422) or to the authorities he quotes; yet I cannot but congratulate myself that a mistake of mine should have provided Sir Clifford Allbutt with an opportunity of emphasising my point in a way which no words of mine could have done, while at the same time reminding the profession of his classic contribution to the *Practitioner* of 1869. I regret that I do not possess a copy, but my recollection of it is that of an original and valuable advocacy of "morphia" hypodermically—and as distinguished from opium—in various forms of cardiac distress, with a note near the end upon dyspnœa; but I do not recollect that special reference was made to the violent paroxysms I referred to as cardiac asthma. The *St. George's Hospital Gazette* for 1909, I am sorry to say, I have not seen.

Had I been less intent on compressing my paper into a small space I should have recorded, at any rate, some of the references I discovered, and explained why few, if any, of them seemed quite to meet my experience in the use of opium (morphine, omnopon, and nepenthe hypodermically seem equally efficacious), in Cheyne-Stokes respiration, and cardiac asthma. Further, I should have explained why several eminent authorities who were good enough to read my paper before it was completed, and but for whose encouragement it would never have been written, considered that the cases recorded struck a note which might be useful both scientifically and clinically at the present juncture, when this use of opium does not appear to be generally recognised—three points, all of which were endorsed in the discussion that followed the reading of the paper.

But I have no wish to claim priority, and offer my sincere apologies to all to whom I may have unwittingly done an injustice, and specially to Sir Clifford Allbutt, to whose pioneer work in this, as in so many fields of medicine, I, in common with the rest of the profession, owe so much. On one point, however, raised by Sir Clifford Allbutt's letter I should like to express a view. "Cardiac dyspnœa" is a large subject which may be subdivided; and opium (or morphine) is, in my experience, chiefly of value in the paroxysmal forms which have but little reference to immediate effort. To one of these forms the term "cardiac asthma" has always seemed to me to be appropriate. It suggests a definite and familiar clinical syndrome which seems to require a designation. "Cardiac dyspnœa" includes much more, while "paroxysmal cardiac dyspnœa" is needlessly long, fails to suggest the violence of the seizure, and includes the major phases of Cheyne-Stokes breathing. Though there may be good reasons for insisting that the word "asthma" shall be confined to "a totally different clinical series," the term "cardiac asthma" has been adopted by Mackenzie and by other cardiologists, and is finding its way into the indices of the more recent text-books. It is convenient, everyone knows what it means, and, whether it is right or wrong, I think it has come to stay.

I am, Sir, yours faithfully,

Tunbridge Wells, Dec. 29th, 1923. CLAUDE WILSON.

AUTO-PYO-THERAPY.

To the Editor of THE LANCET.

SIR,—I could not give a summary of my investigations into auto-pyo-therapy [1] better than that which appeared in THE LANCET of Sept. 29th (p. 660), but I should like to add a few words to indicate the significance which I myself attach to these observations. Not only in the article with which you dealt but also in my first paper (German Assoc. of Surgery, 1922; see Arch. f. klin. Chir. Kongressband, 1922, 121, p. 33) I laid stress on the fact that the importance of my findings lay not in the practical successes (the knife is a very good remedy for suppurations) but in the two theoretical inferences: (1) that subcutaneous injections of untreated "native" pus containing virulent germs cause no progressive infiltration, phlegmon, or sepsis in the same patient; (2) that an established purulent process *can be healed* by such injections without any operative opening of the focus. The old advice "ubi pus, ibi evacua" expressed dogmatically the idea that pus must be the noxious principle of inflammation, and that complete and rapid evacuation was therefore the only real treatment. But practice showed that the application of this axiom could lead us astray; for instance, the much-discussed treatment of peritonitis by large "heroic" laparotomies, cross-incisions (Israel), &c., had very bad results, and supporters of "closed" treatment of peritonitis increase from day to day. Early thoracotomy in empyema carries a notorious risk; Renaud affirms that only such patients recover whose illness was recognised late, so that operation was retarded. Even nowadays the advisability of radical operation in acute osteomyelitis is problematical, being denied

[1] Deut. med. Wochenschrift, August 31st, 1923.

by many authors. The fact becomes increasingly accepted that a kind of preparatory process of the organism must occur in our work. But it is also well known that sometimes *perfect healing* can result from the action of the organism itself. Big peri-appendicular abscesses can be healed without incision or perforation so perfectly that hardly any trace is found on the occasion of a secondary appendectomy. It was my purpose to activate and increase these powers in every case of purulent inflammation. I sought a stimulus or protoplasm activator which might surpass other vaccine treatments as regards the specialty, the intensity, and the multifariousness of its effect, and I think I have found it in the pus itself. In the pus there are found the material and products both of the bacteria and of the cells of the body. The results obtained in my own cases were very good, but I yield to no one in my desire for thorough re-examinations, rigorous choice of cases, and strict indications. For the present I wish this method to be neither a substitute nor a successor to the old, well-proved surgical treatment.

I am, Sir, yours faithfully,

Budapest, Dec. 15th, 1923. DR. ENDRE MAKAI.

HAD OLIVER GOLDSMITH A MEDICAL DEGREE?

To the Editor of THE LANCET.

SIR,—Where Goldsmith graduated as a bachelor in medicine has long been in dispute, but that dispute cannot be settled by the statement of Mr. Justice Samuels in the note on pages 75–76 of his interesting work, "The Early Life, Correspondence, and Writings of the Rt. Hon. Edmund Burke, LL.D." (Cambridge, 1923). In the note referred to Mr. Justice Samuels says: "Goldsmith's medical degree was not, as has been the tradition, obtained at Leyden or Louvain, but at Dublin, where the degree of bachelor of medicine was granted to him, and that Oxford conferred the M.B. *ad eundem* on him on February 17, 1769." The evidence in support of this statement is contained in the following extract from *Jackson's Oxford Journal* for Saturday, Feb. 18th, 1769. "Yesterday Oliver Goldsmith, Esqr., Bachelor of Physic of the University of Dublin, author of 'The Traveller a Poem,' of 'The Present State of Polite Learning in Europe,' and several other learned and ingenious performances, was admitted in Congregation to the same Degree in this University."

Goldsmith entered Trinity College, Dublin, on June 11th, 1745, and he graduated Bachelor in Arts on Feb. 27th, 1749, so that according to the Statutes of the University he would not be eligible for a degree in medicine till 1752. In the latter part of that year Goldsmith left Ireland and entered on the study of medicine in the University of Edinburgh, and two years later he went abroad to complete his education. The first time that Goldsmith is recorded as having described himself as M.B. is on March 31st, 1763, in an agreement, written in his own hand, with James Dodsley. In the interval between his setting out for Edinburgh in the autumn of 1752 and March 31st, 1763, there is no evidence that Goldsmith was in Dublin, and consequently, if he was examined for the degree of M.B. in the University of Dublin, that examination must have been in the year 1752. At that time the examinations for medical degrees in the University were conducted by the College of Physicians, and the names of those examined are recorded in the minutes of that College. In neither the minutes of the College of Physicians nor in those of the Board of Trinity College is there any reference to such an examination of Goldsmith.

If Goldsmith were admitted M.B. by the University of Dublin between 1753 and 1763, that degree must have been conferred in absentia, and without previous examination. On Feb. 5th, 1761, the President and Fellows of the College of Physicians declined to take any further part in the examination of candidates for the medical degrees of the University of Dublin, on the ground that the Board of Trinity College had admitted a person to the degrees of M.B. and M.D. though the College of Physicians had refused to examine him. Had the Board granted a degree in absentia and without examination to Oliver Goldsmith, that fact would probably have been mentioned to strengthen the case of the College of Physicians, but it was not. On May 16th, 1761, the Board of Trinity College unanimously resolved "That a previous examination of the candidates for degrees in medicine is absolutely essential," and, in consequence of the attitude of the Fellows of the College of Physicians, that "The Prælectors in Chymistry and Anatomy, together with the Professor of Medicine," were to conduct the examinations. The Prælector in Anatomy, Dr. Robert Robinson, who, as a Fellow of the College of Physicians, refused to take part in the examinations, was on June 29th dismissed from the office. In view of this resolution it is unlikely that the Board of Trinity College would have admitted, in absentia and without examination, Oliver Goldsmith to the degree of M.B. during the interval between 1761 and March 31st, 1763. It is, of course, possible that this was done, but it is unlikely, and without further evidence in support of it the case for Goldsmith's medical degree in the University of Dublin must be regarded as not proven.

I am, Sir, yours faithfully,

T. PERCY C. KIRKPATRICK,
Registrar, Royal College of Physicians of Ireland.

Dublin, Dec. 23rd, 1923.

WHITE MEN AND WORK IN THE TROPICS.

To the Editor of THE LANCET.

SIR,—In the *Archiv für Schiffs- und Tropen-Hygiene* (vol. xxvii., 5, p. 177) Dr. H. W. Knipping, of the Physiological Institute of the University of Hamburg, discusses the heat regulation of the human body in the tropics, inquiring whether white workmen, who suffer more often from heat-stroke than do natives, have greater difficulty than these others in adjusting themselves to tropical conditions. He shows that after numerous investigations by many men, there has been found no material difference in the heat-regulating mechanisms of these two classes, though coloured men have probably more sweat glands and larger cutaneous capillaries. The great reducer of temperature is perspiration, but that does not help as it might unless there is a sufficient current of dry enough air to evaporate the sweat secreted. As an example of the absolutely worst place in which to work in the tropics he takes a boiler-room (furnace-room, stoke-hold) in the Red Sea, and observes that there, with a temperature of 49° C. (120° F.) and a relative humidity of 88 per cent., men drank, in a four hours' watch, 5 litres, and that 2½ litres were to be evaporated through lungs and skin. Probably this means that 2½ litres of urine were passed, but that is not directly stated. To evaporate this 2½ litres, 1343 calories are claimed as necessary, and 300–400 cubic metres (10,000–14,000 cub. ft.) of air at this humidity to carry this vapour away. There was not enough air supplied, so the men's temperature rose; sometimes he found it as high as 38·8° C. (101·8° F.). Even here it was not men in good health who took care of themselves who got heat-stroke. Coloured firemen escape because they do not work so hard; they do rarely more than half a white man's task. Their modest demands on life are satisfied with less exertion. The white man trying to work in the tropics as he could and did in the temperate zone exposes himself to a great risk. Dr. Knipping reaches the conclusion that, for any climate, the maximum safe output of work is a function of the drying power of the air, in relation to the temperature of the atmosphere and its rate of movement.

A very important question in reference to colonisation is raised by this communication.

I am, Sir, yours faithfully,

R.N.

Obituary.

LAURISTON ELGIE SHAW, M.D., F.R.C.P. LOND.

Dr. L. E. Shaw, consulting physician to Guy's Hospital and to the Royal Bucks Hospital, died at his residence in Weybridge on Christmas Day last, aged 64. He was born in 1859, a son of Dr. Archibald Shaw, of St. Leonards, and received his medical education at Guy's Hospital, where he obtained the gold medal in medicine. In 1881 he obtained the M.R.C.S. Eng.; the following year he graduated in medicine at the University of London, and proceeded to the M.D. in 1883. About this time Dr. Shaw joined the staff of Guy's Hospital and rapidly won his way to promotion, throwing himself with enthusiasm into improving the organisation and teaching in the medical school. He filled the offices of curator of the museum, medical registrar, and teacher of pathology, and later was appointed lecturer in practical biology and assistant physician. In due course he became full physician and lecturer on medicine, posts which he held until his resignation in 1919. He also held office as Dean of the Medical School of Guy's Hospital and was for a time assistant physician at the City of London Chest Hospital.

As a teacher Dr. Shaw was very popular; students greatly appreciated the trouble he took with them, and many owe a sound knowledge of clinical medicine to him. He had a way of bringing out the essential feature of any case, and he not only taught from his own knowledge but criticised the current doctrines fairly, so as to prevent his listeners from pursuing will-o'-the-wisps; he stimulated discussion among those at the bedside and would often ask one of his colleagues to come and discuss a difficult case with him before an assemblage of students. With the help of his friend, Sir Cooper Perry, he wrote a long paper in the Guy's Hospital *Reports* on diseases of the duodenum, which contained the experience of Guy's Hospital ever since post-mortem records had been kept—a paper which has become classical.

Lauriston Shaw became keenly interested in medical politics at an early stage of his career, and associated himself with the British Medical Association. He was elected President of the Metropolitan Counties Branch of the Association in 1911, and was for some years chairman of the Ethical Committee. He took an active part in framing the provisions of the National Health Insurance Act, and held the responsible position of treasurer of the Panel Committee for London from its inception. To this post he was unanimously re-elected year by year, until ill-health compelled his retirement, much to his own regret, in October, 1923. At the same time he resigned his membership of the London Insurance Committee, on which body he had been an appointed representative of the profession.

In appreciation of his unselfish labours for the betterment of medical administration, his colleague, Dr. H. H. Mills, writes: "I was intimately associated with Dr. Shaw during the difficult months immediately before and after the establishment of the National Insurance Act. During that stormy time he remained calm and unperturbed. He was a man of vision and high ideals, which enabled him to take an optimistic view, with never a doubt as to the ultimate success of the great experiment. His calm counsel was invaluable, and his ability in seeing the question from all points of view was remarkable. This enabled him to adjust many difficulties and to make progress even when clashing interests threatened unavoidable rupture. His statesmanlike work was invaluable, and he lived to see the undoubted success of the scheme for which he sacrificed so much."

From the time of his nomination to a seat on the Metropolitan Asylums Board by the Ministry of Health in 1915 until last summer Dr. Shaw had devoted himself unsparingly to the furtherance of the Board's work, and especially to the advancement of its medical status. His knowledge of medical subjects, combined with a capacity for rapidly marshalling facts and a remarkable facility of expression, made him an ideal chairman of the important special and medical subcommittee of the infectious hospitals section. He had a great belief in the potentiality of the Board as an educational organisation, and realised the wealth of material for teaching and research collected in its numerous and varied institutions. He was largely instrumental in instituting both the scientific advisory committee, a body of experts in various branches of medical and allied sciences nominated at the request of the Board by the Medical Research Committee, and also the subcommittee concerned with the coördination of the whole medical and nursing arrangements.

Of his personal qualities "W. H.-W." writes: "Perhaps his most obvious characteristic was his honesty. However he might differ from his colleagues in some matter of policy, they always knew that he advocated a particular course because he believed that it was the best not for himself but for the general good. Nevertheless, he recognised that others might with reason hold contrary opinions; he never got angry, and was always fair to and willing to listen to his opponents. He made an admirable chairman, in which position he exercised a sweet reasonableness and quiet humour that could convert what might have been a stormy meeting into a peaceful, harmonious, and useful discussion."

As a loyal friend, as a sound clinician, and as a man of vision his loss is a sore one to the ranks of medicine. Ever courageous, Shaw carried out his ideals fearlessly in spite of ill-health or adverse criticism, for, as he once admitted, his work in behalf of the National Health Insurance from 1911 to 1913 made him so unpopular that for a time nearly every avenue of activity was closed to him. Notwithstanding all he persevered, and his work during the last ten years in the interests of the community first and of the profession second, won him admiration and respect.

SIR LAMBERT HEPENSTAL ORMSBY, M.D. DUB., F.R.C.S.I.

Sir Lambert H. Ormsby, past President of the Royal College of Surgeons in Ireland, whose death we have already announced, was born in 1850. He had been ill for some weeks past, but had been confined to his bed for only a few days.

Lambert Ormsby, though of Irish descent, was born in Auckland, N.Z., his father, George Owen Ormsby, C.E., being surveyor-general of New Zealand. The son came to Ireland at an early age, and entering the Royal College of Surgeons as an apprentice of Mr. (later Sir) George Porter, had passed all examinations for his licence at the age of 19. Having received the licence he entered Trinity College, Dublin, and subsequently gained the medical degrees of that institution, M.B. in 1874 and M.D. in 1877. He was admitted a Fellow of the Royal College of Surgeons in Ireland in 1875. Meanwhile, at the age of 21, he was elected surgeon to the Meath Hospital, the duties of which post he continued to perform up to his death. From 1902 to 1904 he was President of the Royal College of Surgeons, and on the death of Sir Charles Cameron a few years ago he was elected honorary secretary of the College. During his tenure of office as President, in 1903, Ormsby had the honour of knighthood conferred upon him. Early in his surgical career he became interested in the diseases of children, and was for many years senior surgeon to the National Children's Hospital, Dublin, which in 1876 he had founded as the National Orthopædic and Children's Hospital. His work there is embodied in two important volumes on "Deformities of the Human Body" and on the "Diseases Peculiar to Children." His name is recorded in the history of anæsthetics by his invention of an ether inhaler, which still has its uses, though lacking the niceties of later modifications. He also invented a new form of pile clamp and an aseptic glass drainage-tube. A

description of his new form of rectal speculum was published in THE LANCET, 1905, vol. ii., p. 362. He wrote various papers on surgical subjects, and also a "History of the Meath Hospital." For many years he interested himself in public life, and was an active magistrate and Poor-law guardian. He acted as chairman of the Association for the Housing of the Very Poor in Dublin, and played a prominent part in many philanthropic movements. In 1885 he founded the Dublin Red Cross Nursing Sisters' Home and Training School for Nurses, an institution to which he devoted his constant care. He was consulting surgeon to the Drummond Military Schools, Chapelizod, and honorary consulting surgeon to the Dublin branch of the Institute of Journalists. He was also a member of the Board of Superintendence of Dublin Hospitals, and governor of the Government Lock Hospital.

Sir Lambert Ormsby was a man of strong personality. In 1906, when senior surgeon to the Meath Hospital and the County of Dublin Infirmary, he voiced the grievances of the Naval Medical Service to his students, urging them, in effect, not to enter the service in order that the authorities might be moved to remedy what he considered obvious defects in the system. Although several of his statements were challenged, a committee was formed in 1911 under Admiral Sir John Duncan to inquire into the prevailing conditions, and certain improvements resulted, including the establishment of a naval medical school. In March, 1915, he was appointed honorary consulting surgeon to the New Zealand Expeditionary Force, with the rank of Lieut.-Colonel.

His first wife, daughter of Mr. John Dickinson, died in 1911, leaving a daughter and a son, Colonel G. J. A. Ormsby, D.S.O., R.A.M.C., who distinguished himself in the war. Sir Lambert Ormsby married, secondly, in 1921, Geraldine Matthews, R.R.C., O.B.E.

SIR NAPIER BURNETT, K.B.E., M.D. GLASG., F.R.C.S. & P. EDIN.

Sir Napier Burnett, who died on Christmas Day at the age of 51 years, will be remembered as a real friend to the voluntary hospital principle. He was the youngest son of James Burnett, of Fraserburgh, and was educated at the Universities of Edinburgh and Glasgow, qualifying in medicine at the latter in 1894. He practised in Milnathort for a couple of years, after which he moved to Blackburn, where he built up a large connexion. But general practice did not satisfy him completely and he took up the study of obstetrics and gynæcology at Dublin and Manchester with a view of consulting work in Newcastle-upon-Tyne. In 1905, after taking the F.R.C.S. Edin., he joined the staff of the Women's Hospital in Newcastle and in 1911–12 he was president of the Newcastle Clinical Society, playing an active part in that society's work, especially in the founding of a journal of its Transactions. He was also an original member and part founder of the Pathological Club in Newcastle. His writings at this time included a study of obstetrics in relation to allied sciences, and papers on placenta prævia, *B. coli* infection of the urinary tract in pregnancy, and chorio-angioma of the placenta, the last in association with Prof. Stuart McDonald.

When war broke out in 1914 Burnett was already regarded as something of an authority on hospital administration, of which he had been for years a keen but friendly critic. With Prof. Rutherford Morison he organised the Northumberland War Hospital and was an active member of its surgical staff until he was called to larger things. It was a happy inspiration which led the War Office to invite Burnett to examine war hospitals as to their working efficiency, and he threw himself with much zeal into his duties as chairman of the Economic Committee of the Army Medical Department. When this came to an end he was asked by Sir Arthur Stanley to direct the Hospital Service Department of the Red Cross, which was then undertaking a survey of hospital finance and shortly after he became chief executive officer of the Joint Council, as well as adviser to the Joint War Committee on the administration of the balance of funds to ex-Service men. On behalf of the British Red Cross Society he attended the meetings at Geneva of the League of Red Cross Societies and he also represented the Government at the disposal of Red Cross stock left at Constantinople. Four annual reports on the Voluntary Hospitals in Great Britain (excluding London) issued from his pen, the last of these in July, 1923. These reports are much more than statistical summaries, they are a record of the recovery of the voluntary hospitals from the trough of depression, amounting almost to bankruptcy, in which the war left them. Burnett recognised the deepening interest of the public in the voluntary movement. It may seem strange that little in his professional life previous to the war had foreshadowed the powers which were in the man, but those who knew Burnett well had always seen him as one who touched life at many points and who brightened and quickened what he touched. No doubt among professional men there are many potential administrators whose gifts are never put to the test; the opportunity came to Burnett and did not find him wanting. His balance and persistency, his gift of sound judgment and foresight, his faculty of mastering experiences by a steady sweeping progress of comprehension brought him unerringly to his goal, while the fact that he never stooped to subterfuge or feared the judgment of his fellows brought him the respect even of those who differed from him.

In civic life Burnett was a justice of the peace for the City of Newcastle and sat regularly on the local bench. He became a member of the Newcastle City Council for St. Thomas's Ward, where he was succeeded by his friend Dr. R. W. Simpson when he left for London. In politics a Liberal, in religion a Presbyterian, his standard of public duty was high. It was in large measure his sympathy with the poor, and his acquaintance with their struggles when afflicted with illness, that induced him to work for hospital coördination and efficiency. His own bent was against State control, and while he worked unceasingly to set up sound finance and administration he always hoped that the civil hospitals might remain apart from departmental management. The success of this achievement—if indeed it has been achieved—lies largely at his door.

Sir Napier Burnett married Jane, daughter of the late George McCoull, of Ovington House, Northumberland. He is survived by his widow and four daughters, for whom great sympathy is felt at their untimely loss.

ERNEST ROCK STREETEN, M.R.C.S. ENG.

Dr. E. R. Streeten died on Dec. 17th, 1923, at Bexhill-on-Sea, aged 57 years, after a long period of ill-health. He was a student at St. George's Hospital and qualified M.R.C.S. Eng. and L.R.C.P. Lond. in 1890. After holding an appointment at the Royal India Asylum as assistant medical officer and working as locum and assistant for some time, he bought a practice in Barnsbury, London, N., and remained there for 23 years—until 1918. In that year he had a serious breakdown in health, and owing to cardiac trouble, was compelled to retire from practice. He settled in Ventnor, Isle of Wight, but removed from there to Bexhill-on-Sea early in 1923.

He leaves a widow and one son, aged 15, who is being educated at Epsom College.

A HOVE CENTENARIAN.—On Dec. 27th last Mrs. Dill, mother of Dr. John Gordon Dill, of Brunswick-square, Hove, celebrated her hundredth birthday. She is the daughter of General Sir Charles Wale, K.C.B., and granddaughter of Mr. Thomas Wale, of Little Shelford, Cambridgeshire, who was born in 1701, the three lives thus covering the span of 222 years. Mrs. Dill was married to the late Dr. Richard Dill, of Regency-square, Brighton, in 1856; there were six children of the marriage, Dr. Gordon Dill being the eldest and only surviving son.

Medical News.

UNIVERSITY OF ST. ANDREWS.—At examinations held recently the following candidates passed in the subjects indicated :—

SECOND EXAMINATION FOR DIPLOMA IN PUBLIC HEALTH.
Sanitation and Epidemiology.—James Lamberton, William L. Tullis, and Frances H. Watson.
Sanitary Law and Vital Statistics.—James Lamberton, Isobel M. Mansis, William L. Tullis, and Frances H. Watson.

SOCIETY OF APOTHECARIES OF LONDON.—At examinations held recently the following candidates passed in the subjects indicated :—

Surgery.—D. Dimitrijevitch, Oxford and St. Mary's Hosp.; H. S. Edwards, St. George's Hosp.; and S. Snelson, Manchester.
Medicine.—H. J. Powell, St. Mary's Hosp.; and D. G. Robinson, Guy's and Charing Cross Hosps.
Forensic Medicine.—P. V. Casling, St. Mary's Hosp.; H. T. Chiswell, Guy's Hosp.; H. J. Powell, St. Mary's Hosp.; R. Schofield, Guy's Hosp.; and J. B. Sweet, Glasgow.
Midwifery.—F. H. Armanious, St. Thomas's Hosp.; C. J. Fox, St. Mary's Hosp.; and R. Norrie, St. Andrews University.

The Diploma of the Society was granted to the following candidates entitling them to practise medicine, surgery, and midwifery: D. Dimitrijevitch and C. J. Fox.

A THREE months' course of lectures and demonstrations in Hospital Administration will be given at the North-Western Hospital, Lawn-road, Hampstead, N.W. 3, by Dr. E. W. Goodall, on Mondays and Thursdays, at 4.30 P.M., and alternate Saturdays at 10.30 A.M., beginning on Jan. 7th.

DINNER TO SIR JOHN BLAND-SUTTON.—On Thursday, Jan. 24th, at 7.30 for 8 P.M., at the Hotel Victoria, Northumberland-avenue, W.C., a congratulatory dinner will be given by Middlesex Hospital colleagues and friends to Sir John Bland-Sutton, to mark the occasion of his election to the Presidency of the Royal College of Surgeons of England. Dr. W. Essex Wynter will preside.

CHELSEA CLINICAL SOCIETY.—A meeting of this Society was held in the Clubroom, St. George's Hospital, on Dec. 18th last. A discussion on the Manipulative Treatment of Joint Diseases was opened by Mr. Frank Romer, who also gave a demonstration of the methods employed by bone-setters. Dr. J. B. Mennell and Messrs. Duncan Fitzwilliams, Graeme Anderson, W. H. Trethowan, and B. Whitchurch Howell also took part in the discussion.

RONTGEN SOCIETY.—A general meeting will be held on Jan. 8th, at 8.15 P.M., in the British Institute of Radiology, 32, Welbeck-street, London, W. Dr. J. A. Crowther will read a paper on Studies in X Ray Production, and Mr. H. Moore will speak on the Quality of the X Rays Excited in Hot Cathode and in "Gas" Tubes by Various Types of Generators of High-Tension Current.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART.—A special two weeks' intensive course in cardiology will be held from Jan. 14th to 25th. In the mornings from 10 to 12.30 lectures and demonstrations will be given by Dr. B. T. Parsons-Smith, Dr. J. Strickland Goodall, Dr. John Parkinson, Dr. F. W. Price, Dr. R. O. Moon, and Sir Sydney Russell-Wells, M.P., and the afternoons will be devoted to ward demonstrations and out-patients. A selection of museum specimens, slides, &c., will be arranged in the laboratory and changed daily throughout the course. Further particulars may be obtained from the Dean, Dr. Parsons-Smith, at the hospital, Westmoreland-street, Marylebone, W. 1.

FUTURE OF LEEDS HOSPITALS.—In order to gain the interest of business and professional men in the schemes set on foot for raising more money for the maintenance of the local hospitals and other medical institutions a meeting was held on Dec. 17th at the Leeds Town Hall. Amongst other schemes the collieries in Yorkshire are to contribute on the basis of one farthing per ton of coal raised, and the miners one penny a week each; these together are calculated to realise about £15,000 a year. By other organisations of the business centre of the city it is hoped to raise £2000 a year. These sums, and much more, will be needed, as it is calculated that the deficit on this year's working of the General Infirmary will be between £25,000 and £30,000, while that on the Women's and Children's and Maternity Hospitals will be about £10,000. At the General Infirmary there is a list of 1200 to 1600 people awaiting admission for operations, and to open a new ward would cost between £4000 and £5000 a year. To-day the cost of maintaining the infirmary is £100,000 a year, and £30,000 to £35,000 to carry on the other Leeds hospitals, and for the convalescent homes between £6000 and £10,000 a year.

UNIVERSITY OF LONDON.—A course of three lectures on the Influence of Improved Town Planning and Housing in Public Health will be given by Prof. John Robertson, M.D., of Birmingham, at University College, Gower-street, W.C., on Jan. 18th, Feb. 1st and 15th, at 5 P.M. At the first lecture the chair will be taken by Prof. H. R. Kenwood. The lectures, which will be illustrated with lantern slides, are addressed to advanced students of the University and to others interested in the subject.

REMUNERATION OF INSURANCE PRACTITIONERS.—The Court of Inquiry into the remuneration of practitioners under the National Health Insurance Acts sits to-day (Friday) at the Ministry of Health, and again on Monday and Tuesday, in each case at 10.30 A.M. These meetings are open to the public and the press. The Minister of Health and the Secretary for Scotland have appointed Sir Gilbert Garnsey, K.B.E., to be a member of the Court, in succession to Sir Josiah Stamp, K.B.E., who is unable to serve owing to pressure of other business.

MAUDSLEY HOSPITAL.—The seventh course of lectures and practical courses of instruction for a diploma of psychological medicine will begin on Jan. 21st, 1924, when Sir Frederick Mott, F.R.S., will give the first of eight lectures on the Anatomy of the Nervous System at 2.30 P.M. On Jan. 24th Dr. H. Devine will start his series of eight lectures on Psychology, and on the 25th the first of eight lectures on the Physiology of the Nervous System will be delivered by Dr. F. Golla. Practical instruction and demonstrations will also be given in physiological chemistry and practical physiology. Arrangements for the second part of the course will be announced later. Further particulars may be obtained from the Director of the Pathological Laboratory, Maudsley Hospital, Denmark Hill, London, S.E.

FELLOWSHIP OF MEDICINE.—The North-East London Post-Graduate College is holding in association with the Fellowship of Medicine an intensive course at the Prince of Wales's General Hospital, Tottenham, N. 15, from Feb. 4th to 16th, 1924. It will include demonstrations of clinical methods and cases, lecture-demonstrations, and work in the general and special departments of the hospital. A special feature of the course will be the afternoon lectures at 4.30 P.M. These lectures will be free to general practitioners who are members of the North-East London Post-Graduate College, and to members of the Fellowship of Medicine. The names of the lecturers will be published later, and the complete syllabus will be available shortly. Application should be made to the Dean of the College, Mr. J. Bright Banister, 39, Harley-street, W. 1, or to the secretary to the Fellowship at the above address.

PANEL DOCTORS' £1000 PENALTY.—The report of the Ministry of Health upon the Tottington inquiry, which resulted in a fine of £1000 being imposed upon two medical men in respect of infringements of the Insurance Acts Regulations by charging fees to panel patients, came before the Lancashire Insurance Committee on Dec. 17th. A resolution was moved to request the Ministry to reduce the fine to £100, but only the mover and seconder voted for the resolution. The chairman said that the £1000 went to the Treasury.

CHINESE DOCTOR'S WELCOME IN JAPAN.—Recent signs of a rapprochement between China and Japan have included the enthusiastic welcome during his tour through Japan of Dr. Wu Lien-teh, the president of the National Medical Association of China. Dr. Wu is a Cambridge graduate, who has spent some time in France and Germany and holds many European honours. Now director and chief medical officer of the North Manchuria Plague Prevention Service, and one of the chief authorities on plague, Dr. Wu met important gatherings at Kioto, Tokyo, Osaka, and Nagasaki. At Kioto he spoke to his audience of 400 medical men and students in Mandarin, and specially urged the need in teaching centres of separating the subject of hygiene from the department of bacteriology or even pathology, on the plea that public health has become more important than the lives of individuals. He contrasted the difficulties of Eastern countries with those of Western, owing to differences in constitution and habits, and urged the need of a common standard for health matters in the East. In some centres he spoke in English, his remarks being translated into Japanese by Dr. Todyo. At the Medical Conference at Kagoshima he spoke for one and a half hours to 800 medical men, and dealt particularly with the research work done in Harbin during the past few years. He stated that he hoped that if part of the Boxer Indemnity was returned, as had been proposed, a portion of the money would be devoted to the establishment of a proper institution in China. Throughout his tour Dr. Wu was accorded a warm welcome.

DONATIONS AND BEQUESTS.—Mr. Elgin Needham, solicitor, Werneth, Oldham, by will left £1000 to the Oldham Royal Infirmary, £500 to the Oldham Mission, £100 to the Oldham Nursing Association, £300 to the Oldham Bluecoat School, and £100 to the Ellesmere (Salop) Cottage Hospital.—The late Mr. Walter Laurie, of Hawick, bequeathed £1000 to the Hawick Cottage Hospital, and £500 to the Jubilee Nursing Association. The New Year brought handsome contributions to 22 hospitals in Manchester and Salford from the Lord Mayor of Manchester Two Million Shillings Fund. The gifts ranged from £23,000 to £100, in accordance with the figures appearing in the report of the Joint Hospitals Committee. Some of the larger amounts and their allocations were: Royal Infirmary, £23,000; Children's Hospital, Pendlebury, £9854; Salford Royal Hospital, £8690; Ancoats Hospital, £6000; St. Mary's Hospital, £5355; Eye Hospital, £4743; Hospital for Consumption, £3000; Victoria Hospital, £2464; Hospital for Incurables, £2317; Northern Hospital, £2000; Dental Hospital, £1500.

WATER-SUPPLY OF HASTINGS.—Fourteen years ago, in November, 1909, the ratepayers of Hastings voiced their opposition to a Various Powers Bill to the extent of a majority of 4792 in a poll of 5908. One of the principal clauses in the Bill had reference to the safeguarding of the town's water-supply; during the summer of 1908 the consumption of water for nearly a month was in excess of that which could be obtained by day and night pumping. But the ratepayers' veto prevented anything being done. A cost of some £130,000 was then spoken of, but this sum will now greatly be exceeded in the proposed new Bill which the town council is formulating. In the years that have elapsed neighbouring bodies, both public and private, have been pegging out their watersheds, with the result that Hastings may now have to look as far away as the Eastbourne or Folkestone areas to obtain an adequate water-supply.

LIVERPOOL LOCAL MEDICAL AND PANEL COMMITTEE.—At a meeting of this Committee, held on Dec. 17th, 1923, it was resolved that:—

In view of the fact that the text of the proposed "Provisional Regulations" which become operative on the first of January next has not yet been submitted to Panel Committees, this Committee desires to enter the strongest possible protest against the present arbitrary method of imposing continued and extensive alterations to the Medical Regulations. The Committee wishes to point out that the Medical Regulations were entirely re-cast as recently as the first of January last, and that the profession is now faced with what is practically a new set of regulations. It is quite impossible for a practitioner in active practice to keep in touch with these successive alterations, and he only learns of their existence when he is summoned to appear before the Medical Service Subcommittee.

Four other paragraphs appended to the resolution affirmed the belief of the Committee that the present condition of panel practice may lead to the breakdown of the system.

ULSTER MEDICAL SOCIETY.—The annual dinner of the Society was held in the Medical Institute, Belfast, on Dec. 18th last. Prof. St. Clair Symmers presided, and 137 members and guests were present. The occasion was memorable by reason of the presence of His Grace the Governor of Northern Ireland, the Duke of Abercorn, K.P. There were also present as guests the Prime Minister of Northern Ireland, Sir James Craig; the Lord Chief Justice of Northern Ireland, Sir Denis Henry, K.C.; the Speaker of the House of Commons of Northern Ireland, Hon. Hugh O'Neill; Lord Justice Moore; the President of the Royal College of Surgeons in Ireland, Sir William Wheeler; Mr. Justice Wilson; and the President of the Northern Law Society, Mr. S. G. Crymble. In the course of the evening Sir William Whitla presented a loving cup to the Society. The function was one of the most successful and enjoyable in the history of the Society.

CHILD WELFARE WORK IN LIVERPOOL.—From funds provided by the Carnegie United Kingdom Trust, a central building has been erected to act as a coöperating unit for all agencies concerned in work for mothers and babies. It is also intended to act as a model welfare centre. It contains, besides consulting-rooms and lecture-rooms, two wards of six beds each, in order that children may be kept under observation. The site, gifted by the city, lies between the Royal Liverpool Children's Hospital and the site of the new Maternity Hospital, and should be symbolical of the new centre's work, the aim being to keep mother and child alike healthy and so prevent disease. The upkeep of the new institution falls upon the municipality, but a substantial grant will be received from the Ministry of Health. The building was declared open on Dec. 15th last by Miss Haldane, chairman of the Welfare Committee of the Carnegie Trust, who emphasised the prophylactic character of the work to be begun there in the new year, and appealed for the help of voluntary workers in the welfare movement.

THE RADIUM INSTITUTE.—Sir Malcolm Morris has been elected chairman of the Institute in the place of the late Sir Frederick Treves, and Sir Humphry Rolleston has joined the committee.

GLASGOW WESTERN INFIRMARY.—As the result of a contribution from the Hutton Malcolm Amateur Operatic Society, the Western Infirmary will be able to instal a high tension transformer for use in deep X ray therapy.

GLASGOW ROYAL HOSPITAL FOR SICK CHILDREN.—At this hospital, which comprises 270 beds, during the last year 5171 children were treated as in-patients. In the out-patient department and at the dispensary over a similar period 19,148 and 49,833 respectively were treated, while in the country branch 380 children received attention.

QUEEN CHARLOTTE'S LYING-IN HOSPITAL.—The sixth series of post-graduate lectures to students and practitioners, at 5 P.M. on Thursdays, will be held from Jan. 10th to March 6th inclusive. On Jan. 10th Dr. T. G. Stevens will lecture on the Treatment of Labour Complicated by Generally Contracted Pelvis. On Jan. 17th Dr. C. H. Roberts will speak on Ante-Partum Hæmorrhage. On Jan. 24th Mr. Bright Banister will discuss the Late Manifestations of Puerperal Sepsis. Mr. Aleck Bourne will deal with Puerperal Insanity on Jan. 31st, and Mr. T. B. Davies with Acute Abdominal Pain in Pregnancy on Feb. 7th. On Feb. 14th Mr. L. C. Rivett will lecture on the Value of Antenatal Examination, and on Feb. 21st Mr. Clifford White on Delay in the Second Stage of Labour. Mr. L. G. Phillips will deal with Infant Feeding on Feb. 28th, and the terminal lecture on March 6th by Mr. W. Gilliatt will be on Eclampsia and its Treatment.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, Jan. 8th.

MEDICINE
PATHOLOGY
THERAPEUTICS AND PHARMACOLOGY } at 4.30 P.M.

Joint Discussion:
On the Uses and Limits of Vaccine Therapy. To be opened by Sir Almroth Wright, Dr. A. P. Beddard, Sir William Leishman, Dr. W. Gordon, Dr. Norman McCaskie, Dr. R. Armstrong, and others.

MEDICINE
NEUROLOGY
OBSTETRICS AND GYNÆCOLOGY } at 8.30 P.M.
PSYCHIATRY
SURGERY

Joint Discussion:
On Post-operative and Puerperal Mental Disorders. The following will take part in the discussion: Sir Charters Symonds, Dr. James Collier, Mr. Aleck Bourne, and others.

Thursday, Jan. 10th.

NEUROLOGY: at 8 P.M. at the Hospital for Epilepsy and Paralysis, Maida Vale, W.
Clinical Meeting.

Friday, Jan. 11th.

CLINICAL: at 5.30 P.M. (Cases at 5 P.M.)
Cases will be shown.

OPHTHALMOLOGY: at 8.30 P.M. (Cases at 8 P.M.)
Cases will be shown.
Papers:
Lieut.-Colonel Herbert: A Case of Very Chronic Sympathetic Ophthalmia.
Mr. Harrison Butler: The Practical Value of the Slit Lamp.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos-street, Cavendish-square, W. 1.
FRIDAY, Jan. 11th.—8.30 P.M., Dr. Gordon Holmes will open a discussion on the Examination of the Cerebro-spinal Fluid in Relation to the Diagnosis and Treatment of Neuro-syphilis. Dr. T. Grainger Stewart, Dr. Panton, and others will continue the discussion.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W. 1.
(Lectures, Jan. 7th to 12th.)
NORTH-EASTERN FEVER HOSPITAL.
WEDNESDAY and SATURDAY.—11 A.M., Dr. Frederic Thomson: Diagnosis and Treatment of the Acute Infectious Diseases.

ST. PETER'S HOSPITAL FOR STONE.
MONDAY.—2 P.M., Mr. Andrews: Injuries of the Urinary Organs.
TUESDAY.—2 P.M., Mr. Joly: Urinary Calculi and Calculous Disease.
WEDNESDAY.—2 P.M., Mr. Morson: Tumours of the Urinary Tract.
THURSDAY.—2 P.M., Mr. F. J. F. Barrington: Non-tuberculous Infections of the Urinary Tract.
FRIDAY.—2 P.M., Sir John Thomson-Walker: Urinary Obstruction.
SATURDAY.—2 P.M., Mr. Harkness: Urethritis in the Male.

THE INFANTS HOSPITAL.
2–3.30 P.M., Clinical Demonstration each day.
MONDAY.—4 P.M., Dr. E. Pritchard: Principles of Infant Dietetics.
TUESDAY.—4 P.M., Dr. D. Paterson: Infections of the Urinary Tract.
WEDNESDAY.—4 P.M., Dr. Mackay: Cerebro-spinal Meningitis.
THURSDAY.—4 P.M., Dr. V. Deane: The Teeth of Infants.
FRIDAY.—2 P.M., Round-Table Clinical Consultation. 4 P.M., Dr. W. E. Robinson: Cough.

WEST-END HOSPITAL FOR NERVOUS DISEASES, at 73, Welbeck-street, W. 1.
MONDAY.—1.30 P.M., Dr. H. Campbell: Headache and other Sensory Disturbances.
WEDNESDAY.—5 P.M., Mr. L. Rea: The Eye in Nervous Disease.
FRIDAY.—5 P.M., Dr. C. Worster-Drought: Varieties of Neuro-syphilis.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.
MONDAY, Jan. 7th.—10 A.M., Mr. Maingot: Surgical Pathology. 12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Mr. Addison: Surgical Wards.
TUESDAY.—12 noon, Dr. Burrell: Chest Cases. 2 P.M., Mr. Sinclair: Surgical Out-patients. 2 P.M., Mr. Banks-Davis: Diseases of Throat, Nose, and Ear.
WEDNESDAY.—10 A.M., Dr. Saunders: Medical Diseases of Children. 2 P.M., Dr. Burnford: Medical Wards. 2.30 P.M., Mr. Donald Armour: Surgical Wards.
THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Dept. 12 noon, Mr. Simmonds: Demonstration of Fractures. 2 P.M., Dr. Scott Pinchin: Medical Out-patients.
FRIDAY.—10 A.M., Dr. Drummond Robinson: Gynæcological Operations. 12 noon, Mr. Endean: Venereal Diseases. 2 P.M., Mr. Sinclair: Surgical Out-patients.
SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.
Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

ST. MARY'S HOSPITALS, MANCHESTER, POST-GRADUATE LECTURES.
FRIDAY, Jan. 11th.—(At Whitworth-street West Branch.) 4.30 P.M., Dr. Fletcher Shaw: Some Clinical Points in Obstetrics.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES. (At 3.30 P.M.)
MONDAY, Jan. 7th.—(At the Children's Hospital.) Mr. Thurstan Holland: X Ray Diagnosis.
TUESDAY.—(At the Southern Hospital.) Dr. Macalister: Intersexuality in Relation to Disease.
WEDNESDAY.—(At the Northern Hospital.) Mr. Simpson: Some Points in Abdominal Surgery.
THURSDAY.—(At the Stanley Hospital.) Mr. Courtenay Yorke: Ear, Nose and Throat Cases.
FRIDAY.—(At the Royal Infirmary.) Mr. Jeans: Urinary Surgical Cases.

QUEEN CHARLOTTE'S LYING-IN HOSPITAL, Marylebone-road, N.W.
THURSDAY, Jan. 10th.—5 P.M., Dr. T. G. Stevens: The Treatment of Labour complicated by generally contracted pelvis.

Appointments.

BISSET, Dr. MARY, has been appointed Medical Officer for the County Council Schools at Brighton.
DUNSCOMBE, N. D., M.B., B.Ch., D.P.H. Camb., Casualty Officer at the East London Hospital for Children and Dispensary for Women, Shadwell.
GÖTHE, WERNER, M.R.C.S., L.R.C.P. Lond., Medical Officer in Charge of the Physico- and Electro-Therapeutic Department, Middlesex Hospital.

Vacancies.

For further information refer to the advertisement columns.

Barnet, Wellhouse Hospital.—Asst. Res. M.O. £150.
Dorset Mental Hospital, near Dorchester.—Deputy Med. Supt. and Pathologist. £575.
Galloway Royal Infirmary.—Jun. Res. M.O. £125.
Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—H.P. £50.
Hospital for Tropical Diseases, Endsleigh-gardens, N.W.—H.P. £150.
Hull, Anlaby-road Infirmary.—Visiting S. £150.
Kettering and District General Hospital.—Hon. Radiologist.
Leicester Royal Infirmary.—Second H.P. £125.
Maidstone, Kent County Mental Hospital.—Asst. M.O. £350.

Notes, Comments, and Abstracts.

A VISIT TO A LEPERS' COLONY.

BY SIR THOMAS OLIVER, M.D. GLASG., F.R.C.P. LOND.

WHEN in New Orleans in September last along with Dr. Oscar Dowling, President of the New Orleans Board of Health, and Judge Mawr, the District Attorney, I motored from the Southern States City 96 miles to the "leprosarium" at Carville. For nearly the whole length of the journey the road follows the course of the Mississippi, but the river is concealed from view by an unbroken line of high earthworks, or levees as they are called, raised to confine its unruly waters within limits. The road passes through corn and sugar-cane fields, beside rice beds, inundated with water syphoned from the Mississippi through large iron pipes, and here and there past a cotton field, but cotton plantations in Louisiana, compared with the sugar plantations, add little to the prosperity of the State.

On reaching the leprosarium we were received by Dr. Oswald E. Denny, a smart-looking officer, wearing the uniform of the Public Health Service, who had gained experience of the management and treatment of patients by having been in control of leprosy in the Philippine Islands, where, during the 25 years' administration of the islands by the United States, the number of cases of leprosy has fallen from 9000 to 3000.

Description of the Carville Institute.

The Carville Institute is built on the block and corridor system. On the left of the central or administrative building is a row of neat detached villas for the staff. The institution, which is run by the Federal Government, was established 28 years ago by the purchase of a large plantation. The central building used for administrative purposes was the residence of the planter. It is an elegant and well-finished wooden building, and gives evidence of having been a home of wealth and comfort. At present there is accommodation for 175 patients, but before the end of 1924 it is proposed to make room for 500. As an indication of the belief in the contagiousness of leprosy and dread of the disease, I may say that there was at the time of my visit in the institute a male patient who had committed serious crimes, and against whom the evidence was so strong that were he tried he would probably be convicted and the death penalty exacted. But he is a leper, and no judge will try him, nor will any criminal court open its doors to receive him; thus he remains in Carville untried.

There are separate buildings, to the right of the administrative block, for white and coloured patients of different sex, colour, and nationality. The Chinese, for example, are grouped together, as are the Greeks. From a hygienic and medical point of view the buildings are all that can be desired: the operating theatres, X ray rooms, chemical laboratories, and dispensaries are equipped with the latest and best materials.

On the staff are two consulting physicians, Drs. R. Hopkins and P. Howell, of New Orleans; Dr. Denny, the director; two resident physicians, Drs. H. K. Marshall and J. G. Wooley; and a dentist. Dr. Denny is also in charge of the bacteriological department, and directs and controls medical research. I was much impressed by the thoroughness with which everything is done and by the scrupulous attention to even the smallest hygienic details. In addition to an ordinary roadway between the extreme end of the wing of the official residences and the furthest ward to the right of the central block, there runs an elevated wooden platform extremely convenient in wet weather: a similar means of communication exists between the various buildings in which the patients are housed. The sleeping and living rooms of the latter are separated by corridors. The doors of the rooms are in their upper half occupied by a thin sheet of metallic gauze, useful alike for ventilation and as a preventive against mosquitoes. Of the culinary department and its annexes I can only speak in terms of the highest approbation. The lavatory and toilet system calls for a similar compliment.

The Condition of the Patients.

The patients are confined to the grounds, but these are spacious and open. Attempts to escape are seldom heard of. The patients with whom I conversed were, as far as circumstances permitted, satisfied with all that was being done for them. The worst types of facial leprosy I found among the Chinese. A few of the female patients were resting in their rooms, as some of them were the subjects of moderate pyrexial attacks, which frequently come on after midday, attended by ill-defined pains and gastro-intestinal disturbance.

The leprosarium is situated at a respectful distance from other human habitations, amid beautiful and varying surroundings, and everything is done by the medical staff and by the Roman Catholic chaplain, Father Keenan, with his 18 years of service, to make the enforced incarceration as pleasant and as little irksome as possible to the inmates. The latest addition in this direction is a brass band, which did its best to give us a kindly welcome.

To Dr. and Mrs. Denny I take this opportunity of thanking them for the sincerity of their reception and the warmth of their hospitality, and in this I include the other members of the staff.

Newcastle-upon-Tyne.

A SHORT-CIRCUITING OPERATION FOR INTESTINAL STASIS.

Dr. J. C. Watt, of the West African Medical Staff, has published in pamphlet form a study of Intestinal Stasis (London: John Bale, Sons and Danielsson), based upon the teachings of such observers as Panaroli (1654), O'Beirne (1833), Metchnikoff, and Arbuthnot Lane. He holds that intestinal intoxication is a more potent factor in producing degeneration of arterial walls than even the special syphilitic poisons; that it is usually impossible completely to clean out a relaxed bowel; and that the severer degrees of constipation are the most potent causes of many text-book diseases. Dr. Watt endeavours to combat the reluctance of the medical man to admit that any normal structure in the human body may be a source of disharmonious working of the rest. The operation which he proposed is to stitch the last part of the pelvic colon to the upper part of the rectum, afterwards crushing the intervening crest by means of forceps introduced through a transverse slit, and then dividing with scissors the crushed septum. Dr. Watt thinks that this operation would increase the power of impelling fæces at will into the rectum, and would lead to a call to stool three or four times a day. Holding, as he does, the view that stasis only occurs in the normal subject in the pelvic colon, the relief of stasis would necessarily follow. Dr. Watt does not offer experimental or clinical proof of the value of the suggested operation.

OLD ILLUSTRATED MEDICAL WORKS.

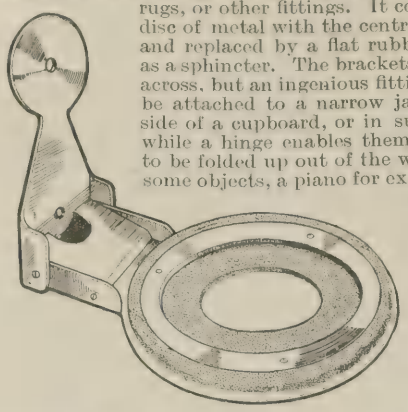
THE new Catalogue of the Internationaal Antiquariaat (Menno Hertzberger, No. 17, of 364 Singel, Amsterdam) records a number of interesting acquisitions now offered for sale to collectors and those interested in old medicine or the history of medicine. The second edition of Celsus, a small folio printed at Milan in 1481, is No. 100 in the Catalogue. This edition, by Pachel and Scinzenzeler, is far rarer than the first. It is finely illuminated, a beautiful copy, tall, clean, and "unwashed," in contemporary stamped binding. The book was not seen by Hain, and is now offered for 460 florins—i.e., something less than £46. Another exceedingly scarce edition offered for f. 325 is the "Herbarius Moguntinus," so-called because first printed at Mainz in 1484. The present edition, embodying the "De Virtutibus Herbarum," of Arnold de Villa Nova, was printed at Venice in 1509, and is one of the oldest herbals illustrated with woodcuts. The Augsburg "Hortus Sanitatis," of the year 1486, is an early printed book offered at the same price as the foregoing. This extremely scarce edition is remarkable for being one of the earliest illustrated books, and is a pioneer work in the history of botany and medicine. Hain does not mention it. John of Kethan's "De Medicina," of date 1517, is a later edition of the "Epiloga en Medicina." These editions were both printed at Seville, and the large woodcuts in the 1517 edition represent the processes of phlebotomy and the body of man and woman, while a smaller cut is a representation of two physicians with their medical boxes. The "Regimen Sanitatis," with commentary by Arnold de Villa Nova, is now offered. The date is circa 1492; it is an apparently unknown edition, the price being f. 160.

Among more modern works in this tempting catalogue we find the curious large atlas by Gautier D'Agoty, printed at Nancy in 1773, with title "Cours Complet d'Anatomie." It consists of 15 large folding plates, and is an early instance of printing in several colours. The two plates of the body of man and woman, which are nearly always lacking, are contained in this volume. The woman with a blue fillet in her hair may have been a live person known to D'Agoty, though she is displayed as if dissected. Old illustrated anatomies have, indeed, quite a human interest of their own, and the lady with the hairband might be paralleled by the well-known Albinus and Maclise illustrations, which are good examples of the figure-drawing of their day and doubtless, in many cases, represented living artists' models. In this connexion we may mention the portrait of a dead man on the reverse of the Cheselden Medal, presented in old days—if not now—at St. Thomas's Hospital. This

represented, as tradition averred, the most perfect corpse ever seen in the dissecting-room at that hospital. We are for the moment unaware if Choulant throws light on this subject. His "History and Bibliography of Anatomic Illustration in its Relation to Anatomic Science and the Graphic Arts" is now offered for f. 37.50. It is Frank's edition, printed at Chicago in 1921. Choulant published the original work in 1852.

A USEFUL BRACKET.

THE illustration shows a convenient bracket for firmly holding a tumbler of practically any size, a bottle, or other vessel, without danger of spilling the contents on cushions, rugs, or other fittings. It consists of a circular disc of metal with the central portion removed and replaced by a flat rubber ring which acts as a sphincter. The brackets measure 4½ inches across, but an ingenious fitting enables them to be attached to a narrow jamb of a door, the side of a cupboard, or in such-like situations, while a hinge enables them, when not in use, to be folded up out of the way. In the case of some objects, a piano for example, the brackets can be swung, when necessary, entirely out of sight. For invalids' chairs and ambulances these brackets should be of much utility, while for motor-cars, caravans, railway carriages, and indeed in any moving vehicle, the invention can be used with great convenience. The brackets are finished in lacquered brass, nickel plate, or oxidised metal, and are obtainable from the Burtons Patents Limited, 82, High-street, Bromley, Kent.



FINGER-PRINTS.

A WORK for the use of students of the finger-print method of identification has been written by Dr. H. Faulds,[1] who has long been known as a pioneer in this subject. In 13 short chapters it deals concisely with the history of the use of finger-prints for the purposes of identification in different parts of the world. Dr. Faulds, in 1886, after his return from Japan, where he made numerous experiments, urged the method on various authorities, including Scotland Yard, and in 1901 Lord Belper's committee recommended the adoption of the method in England and Wales, which took place in July of that year. Since that time not only the patterns formed by ridges and furrows have been studied and classified, but also the pores of the fingers and of the hand and body generally. An advocate of the newest method of poroscopy is Mr. Locard, the police expert of Lyons, who has emphasised that the permanent location of the pores gives proof of personal identity. Dr. Faulds mentions select methods and the necessary chemicals and dusting powders for bringing to view marks on black or white surfaces and objects transparent or opaque, and includes a glossary of terms and several illustrations. These include portraits in the puzzling case of the two American negroes, both named William West, who although unrelated to each other were remarkably alike in almost every detail except finger-prints, which alone saved one from being charged with the offences of the other.

COLONIAL HEALTH REPORTS.

Basutoland.

A CENSUS was taken on May 31st, 1921. The native population was returned as 495,937, exclusive of 17,141 absentees. Females were in the majority by over 50,000. The number of persons to the square mile was 48·30, as against 33·78 in 1904 and 38·97 in 1911. Europeans numbered 1603, as compared with 895 in 1904 and 1396 in 1911. Maseru, the capital and largest town, had a population of 1890 natives and 399 Europeans. The medical work of the territory continues to increase. During 1922, 42,528 patients were treated in the hospitals, and 1207 major and 1008 minor operations were performed. The cry is for more medical men, but in the present financial position of the country (writes Mr. R. B. M. Smith, the Government Secretary) it is not possible to provide them. The medical needs of the country are attended to by ten Government medical officers, two of whom are on specialist duty at the Leper Settlement, and five general practitioners, three of whom are paid district surgeons' fees for attendance at Butha Buthe, Teyateyaneng, and Mokhotlong camps. The missionaries are allowed to dispense simple remedies, but even with their help it cannot be said that the needs of the people are adequately met, though the work done with the Government's limited resources compares favourably with that of other countries. The distribution of free remedies for syphilis continues, and the missionaries who assist in this report most satisfactory results. Typhus fever has become endemic and outbreaks have been reported from every district in the country; 402 cases with 70 deaths were notified by the medical officers. The disease is of a mild nature, and many cases go unreported. It has been found most difficult to arouse the people to a sense of the gravity of the matter, but new regulations are being framed with a view to ensuring prompt notification, disinfestation, and quarantine. Small-pox was reported in all the districts except Maseru. The outbreaks were limited in extent except in Mohale's Hoek; there were in all 421 cases with 46 deaths. Influenza was fairly prevalent, 530 cases with two deaths being recorded. There were 77 cases of pneumonia with six deaths. Dysentery caused two deaths out of 89 cases. The dysentery is of the bacillary variety; amœbic or tropical dysentery is never seen except as an importation. Four cases of cerebro-spinal fever were recorded. The population of the Leper Institution on Dec. 31st, 1922, was 479 (220 males and 259 females); 87 new patients were admitted. It was noted that many were in the early stages of the disease, which is a sign that the objects and benefits of the institution are being appreciated by the people. A number came voluntarily to get admission; ten deserters were readmitted, and, from reports received, there are very few at large now. Five patients deserted during the year—by far the smallest number of deserters on record. All of them were returned promptly by their chiefs or their people, and this has had an excellent effect in the compounds. There were 68 deaths, of which 12 were due to influenza. Treatment with sodium morrhuate and the ethyl esters of the chaulmoogric acid series is being vigorously pushed and the good results obtained are expected to be continued. Improvements are being constantly made in the buildings and precincts of the compounds. Tree planting continues, and the orchards begun last year give promise of being very useful; it has been noted that fresh fruit, besides preventing scurvy, has a beneficial effect in leprosy, no doubt due to vitamin C. Dr. E. C. Long, C.M.G., principal medical officer, went on retirement on Dec. 31st, 1922, after over 32 years' service in the territory. He was succeeded by Dr. N. M. Macfarlane, deputy principal medical officer and superintendent of the Leper Settlement.

Grenada.

Mr. Herbert Ferguson, Colonial Secretary, in his report for 1922, says: "The colony, including the island of Carriacou, has a comparatively low death-rate, especially among adults, and health conditions are generally good. The death-rate for the year was 18·8 per 1000. Intestinal diseases, due to insufficient and improper feeding, are the cause of most of the deaths of children, and although remedial measures are being carried out by the Government and the District Boards, the death-rate among children is high. Of the total deaths 42·6 were of children below the age of 5 years. The death-rate of adults in proportion to the population above 5 years of age is considerably reduced, and, while not so low as in European countries, compares more favourably with the adult death-rate in temperate zones than the total death-rate indicates. Diarrhœa and enteritis caused 329 deaths (4·8 per 1000 of the population), dysentery 83 (1·2 per 1000), and malaria 83 (1·2 per 1000). There is a pipe-borne water service in all the parishes of the island except St. David's, the latter being supplied with numerous protected springs and streams. Certain lands forming the catchment area of the water-supply of St. George's have been acquired by the Government in order to prevent pollution. The water-supply of the island of Carriacou is obtained from wells and from rain-water stored in cisterns. The climate of Grenada can be classed as excellent, especially from December to May, when it is delightful. The trade-winds are steadily prevalent during this period, but occasionally fail in the autumn months, which are somewhat damp and hot. The range of temperature is small and tends to make the climate equable and healthy. The thermometer seldom reaches 90° F. in the shade, or drops below 70°, and these occasions occur so rarely that they are specially recorded in the meteorological notes of the year. The highest temperature in 1922 was 90° and the lowest 68°. The mean of maximum temperatures was 83° and the mean of minimum 73°. The rainfall varies according to altitude.

---

[1] A Manual of Practical Dactylography. By Dr. Henry Faulds. London: Police Review Publishing Co., Ltd., 8, Red Lion-square, W.C. Pp. 68. 2s.

WE have received from the Laboratory of the Products "Usines du Rhone," 21, Rue Jean Goujon, Paris (8e) (Distributing Agents: Messrs. Dick, Coates and Co., 41, Great Tower-street, London, E.C. 3), a useful desk-block calendar for 1924, with a page for each day, on the well-known continental loose-leaf principle, on which reference to future or past dates is equally prompt and easy.

An Address
ON
TYPES OF GLYCOSURIA AND THEIR TREATMENT.

Delivered before the Manchester Medical Society, on Dec. 5th, 1923,

BY W. LANGDON BROWN, M.D. CAMB., F.R.C.P. LOND.,
PHYSICIAN, ST. BARTHOLOMEW'S HOSPITAL.

ALTHOUGH carbohydrate forms more than 70 per cent. of our ordinary diet it seldom constitutes more than 1 per cent. of our body-weight. This simple consideration alone shows that it must be the most easily metabolised of the foodstuffs, and it would naturally lead us to expect that when the process of metabolism is disturbed it will show itself particularly in respect of carbohydrate. That true diabetes implies a great deal more than a mere disturbance of carbohydrate metabolism is easily shown by the fact that if the total amount of food be sufficiently reduced glycosuria will cease, but that addition of too much protein and fat to the diet will cause its return without giving any carbohydrate at all. Again, the culmination of diabetes in coma is not directly due to the sugar at all, but chiefly to disturbance of fat metabolism, though protein and even inorganic salts are also involved. Diabetes is a disease characterised by an exaggerated katabolism, which shows itself first, and most obviously, in respect of that foodstuff which is ordinarily most abundantly ingested and yet forms the smallest part of the bodily tissues.

THE LIMIT OF SUGAR ASSIMILATION.

There is a limit to the amount of sugar which anyone can assimilate, but this limit is high enough for all ordinary needs. A normal individual has to take ¼ per cent. of his body-weight, which means as much as 150 to 200 g. (5 to 7 oz.) of dextrose at one time before any will appear in the urine, but no amount of starch should cause glycosuria because the time taken in its digestion prevents the blood from being flooded with sugar. While the ingestion of sugar may therefore be followed by glycosuria without implying the existence of diabetes, Naunyn declared that anyone passing sugar after even a free ingestion of starch is a potential diabetic. Before accepting that statement without modification, we must consider the mechanism by which the body attempts to compensate for an impaired power to assimilate sugar.

(*a*) It may store more than usual in the more stable form of fat. As von Noorden showed, some cases of obesity merely amount to latent glycosuria. The escape of a valuable foodstuff is thus avoided, but like all pathological substitutes for a physiological method, it is an inferior one. It adds to the dead weight of the body, making activity more difficult, while its complete oxidation makes a greater demand on the already over-taxed energies. Clearly, there must be a limit to this deposit of fat and when this is reached some of the sugar overflows into the urine.

(*b*) The body may raise the threshold for sugar. Normally, the blood contains 0·1 per cent. of sugar. About 20 minutes after a meal containing sugar this begins to rise and may reach about 0·15 to 0·17 per cent., falling again after an hour or more. If this figure is exceeded some sugar will usually appear in the urine. But when sugar metabolism has been impaired for some time the blood-sugar will rise and yet no sugar need appear in the urine. Many treated diabetics may show no glycosuria with blood-sugar as high as 0·25 per cent., a figure at which the normal individual would inevitably excrete sugar.

Here again the pathological compensation is an imperfect one. Whereas, the normal 0·1 per cent. of sugar appears to be in colloid combination, amounts above this appear to be in simple solution—i.e., they act as crystalloids. In this form they raise the osmotic pressure of the blood and disturb the equilibrium of the tissue fluids. Several of the symptoms are due to this. Thus the polyuria and the consequent thirst are mainly due to depletion of the body tissues of water by this rise of osmotic pressure in the blood. More serious results of the same cause are alterations in the translucency of the crystalline lens, causing diabetic cataract, and the changes in the sheaths of the nerves causing neuritis. The liability to septic infections and carbuncle are probably due in the same way to this excess of blood-sugar, which, while reducing the resistance of the tissues, provides an excellent pabulum for bacteria.

Hyperglycæmia and Glycosuria.

But recent experiments by Allen show that hyperglycæmia has an even more fundamental effect, for if it be continued the cell islets of the pancreas swell up, become vacuolated, and ultimately burst their basement membrane. I think this throws light on the old-standing controversy as to whether all cases of diabetes are pancreatic in origin. I am of opinion that they need not originate in the pancreas; but it is clear, wherever they start, if they keep up a sufficient level of hyperglycæmia they will ultimately affect the structure of the pancreas. Presumably the cell islets become exhausted in the attempt to deal with the excess of sugar in the blood, for Allen also showed that by controlling hyperglycæmia the cell islets showed some power of recovery. Since the kidney can interpose a barrier or threshold of varying height to the excretion of sugar, examination of the urine is not a satisfactory measure of the sugar of the blood. Glycosuria may occur without hyperglycæmia, while hyperglycæmia need not be followed by glycosuria. The point of interest in cases of disturbed carbohydrate metabolism has therefore shifted from the urine to the blood, and we can modify Naunyn's phrase as follows: *Anyone with a resting hyperglycæmia is a potential diabetic.* If anything this definition is not inclusive enough, as we shall see. But it excludes cases of renal glycosuria, which belongs to an entirely different category from all other forms of glycosuria, and which do not depend on a disturbance of metabolism at all.

Renal Glycosuria.

The name of *renal glycosuria* has been given on the analogy of the effect of phloridzin poisoning, which seems to act directly on the kidney, causing it to secrete sugar, even when the sugar in the blood has been reduced below normal. I recently had an example of this in a young lady in whom glycosuria was detected in the course of routine examination. Further observations showed that she always passed about the same amount of sugar whatever the diet, the percentage usually lying between 1 and 2 per cent. Her blood-sugar was low and never reached the normal leak-point of 0·15 per cent. even after 50 g. of glycose were administered in one dose, nor did this increase the glycosuria. One may conclude that a glycosuria which keeps at 1 to 2 per cent. independently of diet is of this renal type, and a practical deduction is that such patients should not be put on a restricted diet. It is very difficult, if not impossible, to get them free from glycosuria, but it is easy to cause them to waste and to become ill if such an attempt is made. Doubtless some of the cases of persistent glycosuria without symptoms that are described from time to time are of this class. But I have also had instances of intermittent glycosuria of the renal type. Thus a young man of 21 had glycosuria detected on examination for life insurance and on one occasion afterwards. He had no other symptoms. His blood-sugar was 0·064 per cent., and after 50 g. of dextrose it never rose above 0·12 per cent., falling again to 0·065 per cent. in 1½ hours, without any glycosuria. He evidently had a low leak-point, but when 50 g. of dextrose were given this was not necessarily reached. Another young man, aged 20, showed traces of sugar in the urine on three occasions

on examination as to fitness for work in the East. His blood-sugar was 0·1 per cent. and did not rise above this figure at any time after 50 g. of dextrose. At the end of 1½ hours he passed 0·46 per cent. of sugar and his blood-sugar was as low as 0·05 per cent.

I do not see how it is possible to recognise renal glycosuria of this intermittent type without observing the blood-sugar curve after the ingestion of 25 to 50 g. of dextrose. The cause of lowering the kidney threshold is quite unknown, and although the condition is called renal glycosuria on the analogy of phloridzin poisoning the majority of such cases show no evidence of renal disease. In true nephritis there may be lowering of the threshold, but more frequently it is raised. I consider that such cases of renal glycosuria call for no treatment.

Glycosuria Dependent on Endocrine Disturbance.

I will next deal with types of glycosuria which appear to depend on disturbances of endocrine glands. In order to comprehend these it is necessary to realise that the lowest or vegetative nervous system consists of two mutually antagonistic parts—the *sympathetic* which mobilises the body for defence, converting potential energy into kinetic, and the *parasympathetic* or extended vagus which stores up energy, especially the energy derived from the assimilation of food. Each of these coöperate with endocrine glands, the sympathetic with the adrenals, thyroid, and pituitary; the parasympathetic with the pancreas, and possibly the parathyroids. An important way in which the first group prepare for defence is by mobilising sugar into the blood-stream. Here it is normally utilised for muscular energy if the organism has to defend itself by fight or flight, or it is used for the production of fever. Cramer has shown that this is, at any rate, one of the ways in which fever is produced. If carbohydrate metabolism is normal the sugar is utilised at once, but if it is not there will be hyperglycæmia, though not necessarily glycosuria. Thus hyperglycæmia in pneumonia and rheumatic fever was observed some years ago before its significance was realised. I think we have in this fact the explanation of the influence of focal sepsis in aggravating diabetes. Sepsis will not necessarily cause hyperglycæmia. Thus, in six consecutive cases of recurrent boils I found hyperglycæmia in one but not in the other five. The occurrence of recognisable hyperglycæmia in sepsis indicates an imperfection in the sugar-storing mechanism, and if such an imperfection is already definitely present it will increase it. But it is defensive in origin and aim. In disease we frequently find a perversion of a defensive mechanism, and I look upon a parenchymatous enlargement of the thyroid as very frequently originating thus.

Thyroid Glycosuria and Hyperglycæmia.

I have recently had two striking examples of this disease in lads, where the enlargement was apparently due to a reaction against infection from septic tonsils; in each case the swelling went down considerably immediately after the enucleation of the tonsils, and although there was never glycosuria and no resting hyperglycæmia, the blood-sugar rose to 0·233 in one case, and to 0·21 per cent. in the other an hour after 50 g. of sugar were given, yet there was no glycosuria.

This is still more marked in exophthalmic goitre. I have never investigated the carbohydrate metabolism in this disease without finding a marked rise of blood-sugar following the administration of sugar. There may be no glycosuria because of the rise of threshold, but even the level of the raised threshold may be exceeded and then glycosuria follows. This may occur temporarily from a purely emotional cause. Thus in a severe and ultimately fatal case of Graves's disease in a man I had found marked hyperglycæmia. One day, some time after this, he suddenly passed sugar, and on inquiry I found he had had an emotional shock that day.

Do cases of hyperthyroidism ever develop true diabetes? I think they do if they have hyperglycæmia prolonged enough to damage their cell islets. A girl developed Graves's disease when her father became a prisoner of war in the hands of the Turks. Her condition grew worse as information as to his sufferings arrived, and when he died she was found to be suffering from glycosuria. After preliminary dieting the urine became free from sugar, but I found she had a resting hyperglycæmia of 0·198 per cent., which rose to 0·46 per cent. an hour after 50 g. of dextrose, when she passed 5·25 per cent. of sugar. She did well and kept free from sugar for about a year, when she suddenly went into coma as the result of an intercurrent infection.

An interesting case at present under my observation is that of a young woman with hyperthyroidism of 15 years' standing, which had produced not auricular fibrillation but auricular extra-systoles, which readily yielded to 2 gr. of quinidine sulphate twice a day. Her basal metabolism was + 55 per cent., and recently she had become troubled with fatty diarrhœa, the stools containing 53 per cent. of fat, 45·7 per cent. of which was neutral fat. Her diastase was 50 to 100 units, indicating a definite pancreatic insufficiency since the diastase output is usually lowered in ordinary hyperthyroidism. Her resting blood-sugar was 0·108 per cent., but it rose to 0·286 per cent. half an hour after giving 50 gr. of dextrose and even at the end of one and a half hours it was 0·23 per cent. when she passed 2·6 per cent. of sugar. At other times there was only an occasional trace of sugar. Yet her blood-sugar curve is that of severe diabetes. The following case is an interesting example of glycosuria in treated myxœdema:—

A lady of 55 was sent to see me with the following history. She was apparently one of the earliest cases to be treated by thyroid extract, about 30 years ago. She had taken 5 gr. daily ever since. In June of this year she complained of thirst and dryness of the throat, and her medical man found she was passing nearly 6 per cent. of sugar. On diet and 1 gr. of thyroid a day the sugar fell to a trace and then disappeared when the thyroid was reduced to ½ gr., but she began to get myxœdema again. Any increase of this dose or in the carbohydrate of the diet produced a return of sugar. When I saw her the only signs of myxœdema were a few patches of skin which suggested it, but she was passing sugar and her blood-sugar was very high—0·433 per cent. This seemed an ideal case in which to restore the balance between the thyroid and pancreas by insulin, but unfortunately she has a great prejudice against it. So I put her on Graham's "ladder diet" and allowed 1 gr. of thyroid a day; on this she kept free from sugar and the blood-sugar fell to 0·137 per cent. After a time we were able to increase the thyroid to 2½ gr. daily and maintain her blood and urine normal as to sugar although she was taking 1½ oz. of bread daily. It is worth noting that her father died of diabetes.

I think it is not unusual for patients with long-standing myxœdema to develop glycosuria. At St. Bartholomew's Hospital out of 11 consecutive cases four were found to be passing sugar (Garrod). It is well known that they may become intolerant of thyroid. But such marked hyperglycæmia is, I think, unusual. Even such cases can be successfully treated if alimentary rest is used as an aid to treatment and the dosage of thyroid is regulated with sufficient care. But the following case raises the question in a different and an interesting form:—

The wife of a medical man, aged 32, was worried because she was putting on weight rather rapidly. She therefore started taking 3 gr. of thyroid extract daily at Christmas, 1922, and lost over a stone in weight. In May, 1923, she suffered from palpitations and shortness of breath so she stopped taking thyroid, but her weight continued to fall in spite of rest. In September she became thirsty, had pruritus vulvæ, and was found to be passing sugar in large amounts. I found her resting blood-sugar was 0·38 per cent. I put her on 2½ gr. of quinine hydrobromide three times a day and dieted her by Graham's method. She became free from sugar on the first day of fasting, and when her diet contained 5 oz. of milk and 3½ oz. of bread her blood-sugar was 0·144 per cent. She is still free from sugar on 90 g. of added carbohydrate, but her blood-sugar is 0·153 per cent. and she is still losing weight, so she is starting a course of insulin. The pulse is still rapid and she is a little tremulous, but she has no other signs of hyperthyroidism.

What is the explanation of this case? Personally, I think her increasing weight was the first sign of impaired carbohydrate metabolism, and that taking

the thyroid extract converted her from a case of latent to one of consecutive glycosuria by still further upsetting her metabolism. One thing, however, to which I would specially call your attention is that as a case of Graves's disease improves the threshold may fall faster than the hyperglycæmia, so that I do not worry particularly about the appearance of a certain amount of sugar in the urine if the general condition of such a patient is obviously improving. Thus a woman of about 40 had Graves's disease and developed leukoderma. Her resting blood-sugar was 0·069 per cent., but after 50 g. of dextrose it rose to 0·323 per cent. at the end of an hour, yet she had no glycosuria. She improved very much, and as she did so she occasionally passed sugar. This was about four years ago and I frequently see her and she is apparently well.

The typical blood-sugar curve in hyperthyroidism is a sharp rise reaching its maximum in an hour and then usually a rather sharp fall again, but not reaching normal in one and a half hours (Mackenzie Wallis). In this type of case it is the thyroid rather than the glycosuria which calls for treatment, the essential features of which are rest, physical and emotional, removal of septic foci, particularly in the tonsils and bowels, and administration of quinine hydrobromide in doses of 3 to 5 gr. three times a day. The dietetic restrictions need not be very drastic as a rule.

Adrenal Glycosuria.

The antagonism between the pancreas and the adrenal medulla is well known. It is expressed in such phenomena as Loewi's adrenalin pupillary reaction, and in the dribbling secretion of pancreatic juice which follows removal of the adrenals, a secretion which can be checked by injections of adrenalin. But it is seen most clearly in the opposite effects of adrenalin and insulin on carbohydrate metabolism. That adrenalin injections could produce glycosuria was shown by Blum more than 20 years ago. Later it was shown that the diabetic puncture produced its effect through the adrenals and possibly the pituitary in addition. Severance of the nervous channels between the medulla and the adrenals rendered diabetic puncture inoperative. J. H. Burn has proved that there is no direct antagonism between adrenalin and insulin as there is between pituitrin and insulin. He agrees with the accepted view that adrenalin turns the glycogen of the liver into sugar, thus interfering with the storage mechanism.

As adrenalin raises arterial tension as well as producing glycosuria it is tempting to assume that the glycosuria associated with high tension in later life may be adrenal in origin, especially as it is apt to occur in overworked, worried people. But there is no proof of this. I should, however, like to call attention to the form of the blood-sugar curve in this nervous type of glycosuria. It is characterised by a sharp peak just where the normal curve is rounded. This peak exceeds the threshold, and this is when the glycosuria occurs. It suggests a delay in the storage mechanism coming into action. Now adrenalin is activated through the emotional nervous system and in its turn acts on the sugar-storing process. So that there is at least a prima facie case for investigation of such cases along the line of adrenal glycosuria. It is usually sufficient to deprive such patients of sugar as such while allowing them to take a reasonable quantity of starch. In this way the mechanism for storage of sugar as glycogen is not suddenly overtaxed immediately after food. The process of starch assimilation is a more gradual one. But the most important part of treatment is a holiday and attention to general hygiene.

Pituitary Glycosuria.

This is due to overaction of the pars intermedia of the pituitary. It is often associated with signs referable to other portions of the gland. If the pituitary is enlarged there may be optic atrophy and bitemporal hemianopsia, some interference with the third nerve and X ray evidence of enlargement of the pituitary fossa. If the anterior lobe is overacting there will be signs of acromegaly as well—if it is underactive there will be diminished sexual development, while if the posterior lobe is underacting there will be obesity and diabetes insipidus as well as mellitus. The glycosuria may be intermittent since the pituitary seems to be rhythmic in its functions, while the characteristic of the blood is the slow rise of sugar in it and an equally slow fall, giving a rounded form to the curve. Mackenzie Wallis has called attention to the frequency with which signs of pituitary disease occur in intermittent glycosuria, and has also pointed out the close resemblance between the blood-sugar curve in such pituitary cases and in the glycosuria as distinct from the lactosuria of pregnancy. This confirms the view that the glycosuria of pregnancy is due to the stimulating effect of pregnancy on the pituitary; the curious alteration of the facies in pregnancy resembling a mild degree of acromegaly suggests this also. We now have direct experimental evidence in support of this view. Dixon has shown that injections of ovarian extract stimulated the secretion of pituitrin, while J. H. Burn found that although pituitrin did not in itself cause hyperglycæmia, it was able to inhibit the fall of blood-sugar which would otherwise have followed the injection of insulin. I think, therefore, the statement is justified that the glycosuria of pregnancy is due to its stimulating effect on the pituitary which then directly inhibits the internal secretion of the pancreas. It may well be that in its inception this process is physiological, diverting the stream of sugar from storage in the maternal tissues to the use of the fœtus.

I saw an interesting example of this some years ago in a woman of 42, who looked acromegalic, had hair on her cheeks, a blood pressure of 170 mm., and glycosuria. She was pregnant, and as the pregnancy proceeded the glycosuria became less amenable and she developed hydramnios. Subsequently she was delivered of a living child, after which she remained free from sugar on an ordinary diet. The occurrence of hydramnios is interesting as it is a common complication of pregnancy in true diabetes. Yet pregnancy is not very likely to occur in a diabetic of 42. Some years afterwards she turned up again with diabetes of the ordinary type. I conclude that her pregnancy stimulated a pituitary already tending to be too active, and that afterwards, although she was free from glycosuria for some years, her blood-sugar kept at a sufficiently high level to exhaust her cell islets. Unfortunately, this case occurred before opportunities existed for routine examination of the blood-sugar. The influence of the male gonads on the pituitary I could also illustrate from a remarkable case, but for my present purpose it is sufficient to say that here a testicular graft for atrophy following mumps completely changed the blood-sugar curve.

The combination of glycosuria and Fröhlich's syndrome can only be explained by assuming an overactive pars intermedia with diminished activity of the rest. Thus a man of 50, who had always been fat, and then weighed more than 18 st., was found to have glycosuria. Sexually he was infantile and his blood-sugar curve was of the pituitary type, reaching 0·310 per cent. an hour and a half after the ingestion of 50 g. of dextrose, and still standing at 0·261 per cent. at the end of two hours when he passed 3·6 per cent. of sugar.

Pancreatic Glycosuria.

No difficulty is experienced in recognising cases of glycosuria associated with frank pancreatic disease. There is fatty diarrhœa, due, as in the case already referred to, to an excess of unsplit fats, and there may be creatorrhœa. The output of urinary diastase is increased to 50 units or more and the adrenalin eye test may be positive. Yet how often are such signs found in ordinary diabetes? It is true that they may be present in the early stages or even before glycosuria occurs and subsequently subside. Thus I saw a case of a young lady who had symptoms of

pancreatitis and then glycosuria. She cleared up with dieting for a time and then returned to ordinary food. After that she showed no evidence of pancreatitis but the ordinary symptoms of diabetes, which subsequently proved fatal. Unless one had seen this case in the early stages its pancreatic origin would have been missed.

TRUE DIABETES.

But when full allowance is made for all this, one must admit that the pancreatic origin of true diabetes is still unproven. My own view is that it is due to a more profound metabolic disturbance than that evoked by one endocrine gland. Eppinger, Falta, and Rudinger put forward the hypothesis of a disturbed endocrine balance as the cause. If one endocrine gland were diseased we could understand a loss of balance comparable to that which occurs when a group of muscles is paralysed. But such signs of endocrine disease are lacking in ordinary diabetes even if carefully looked for. It will be noted that the sympathetic stimulates all the endocrine glands which mobilise sugar into the blood—i.e., the thyroid, adrenal, and pituitary—while it probably inhibits the pancreas, either directly or by antagonising the vagus, thus checking sugar storage. Overaction of the sympathetic at any rate means increased katabolism and usually hyperglycæmia. And as hyperglycæmia if not caused by deficiency of the pancreatic cell islets, will at any rate damage them in time, we may admit that all cases of diabetes are ultimately associated with insufficiency of pancreatic internal secretion.

The blood-sugar curve starts above normal, rises very sharply, and keeps at a high level for at least two hours, so that it differs materially from the other curves I have discussed. But to my mind it is seldom necessary to do a blood-sugar curve in what appears clinically to be a clear case of true diabetes, nor is it advisable. This procedure should be reserved for glycosuria of doubtful origin.

Alimentary Rest.

The treatment of diabetes by alimentary rest undoubtedly represented a great advance. I still have cases under my care occurring in young people about 1915, when I started using this method systematically. They appear to be in an arrested state. But metabolically, they are at best among the lame and the halt, while many have fallen by the way. This is because we had no satisfactory method of checking hyperglycæmia with its evil consequences, for though interpolated days of fasting or of vegetable and egg diet have some effect in this direction, that effect is not sufficiently prolonged.

Insulin.

No words of mine are needed to commend insulin, for not only has its discovery proved a theoretical belief long held, but it has been of immense practical value already. I will merely describe my usual procedure with it and then consider some of the limitations of the drug. Throughout I will assume that the opportunities for blood-sugar estimations are present but restricted as they are in general practice. I first put the patient on a 48-hour mitigated fast, allowing soup, beef-tea, tea or coffee, water ad lib., and alcohol in suitable cases. Most cases become free from glycosuria on this. Then I give 48 hours of vegetable and egg diet. If the patient is still free from sugar I put him through Graham's Ladder Diet. At the top of the ladder, or if sugar reappears at any stage of it, I estimate the resting blood-sugar if this has not already been done, and if it is above 0·18 per cent. I give 10 units of insulin daily before breakfast or lunch. If the resting blood-sugar is between 0·14 and 0·18 per cent. I give only 5 units. If it is below 0·14 per cent. I do not regard the case as one for insulin. I like to know the blood-sugar six hours after insulin is given, for the dosage will largely depend on the rate at which it falls. Even if the patient is keeping free from glycosuria on insulin I do not add carbohydrate to the diet for two or three weeks. If not free from sugar on 10 units daily I give a second dose of 5 units, and may increase the dosage to one of 15 and a second of 10 units. I do not often find it necessary to exceed these doses except in actual or threatened coma. I believe that difficulties which appear to call for higher dosage are often due to adding carbohydrate to the diet too soon, when the action of insulin may become uncertain. When conditions appear to have become stable I add 5 oz. of milk to the diet, and two days later add ½ oz. of bread, increasing this by ½ ounces every other day until 4 oz. are reached, provided there is no return of glycosuria and the blood-sugar is keeping within normal limits. I do not trouble about slight returns of glycosuria if the blood-sugar is continuing to fall, as I think the kidney threshold often falls quicker than the hyperglycæmia as the case improves.

If the patient continues to be free from sugar the question will arise whether to diminish the dose of insulin or to increase the diet. If the calorie intake is adequate and weight is being maintained, I diminish the dose of insulin unit by unit until sugar just reappears; then interpolate a day of vegetable and egg diet and after that return to the former diet with 1 unit more of insulin than that on which glycosuria recurred. If the calorie value is low I increase the carbohydrate in the diet while keeping the dose of insulin the same. When sugar just reappears I interpolate a day of vegetable and egg diet, and then return to the former diet with only three-quarters of the amount of carbohydrate taken during the day on which glycosuria recurred. In any case I give a day of vegetable and egg diet once a fortnight. But details must depend on the individual case.

Acute Cases.

As an example of its success, I may quote the case of a little girl with severe diabetes with ketosis of recent origin, and a blood-sugar of 0·42 per cent. She is now keeping free from glycosuria and hyperglycæmia on a diet of approximately 1600 calories including 5 oz. of milk and 1½ oz. of bread without any insulin, and she has never had more than 5 units a day, which was gradually diminished as the blood-sugar fell. For more than a month now she has had no insulin at all, yet the blood-sugar is only 0·065 per cent. Indeed, I have been struck with the extraordinarily good results one may get with insulin in children. It is too early to speak positively, but it appears to me possible if the hyperglycæmia is thus controlled, that as the child grows fresh cell islets come into existence without being damaged as fast as they are formed. In this way the type of case which was previously the most unsatisfactory may become the most hopeful to treat. The following case still under my care suggests, however, that sometimes diet alone may be as successful as when aided by insulin:—

A girl of 26, whose symptoms were of very gradual onset but probably of a few months' duration, had a blood-sugar of 0·26 per cent.; ketosis was present. After alimentary rest she reached the top of the ladder with a blood-sugar of 0·1 per cent. On gradually increasing the carbohydrate intake to 5 oz. of milk and 2½ oz. of bread, which equals 46 g. of added carbohydrate, glycosuria just reappeared with a blood-sugar of 0·14 per cent. She then had a day of vegetable and egg diet which cleared up the glycosuria, and the same plan was repeated with 5 units of insulin daily. Glycosuria reappeared in spite of this when the added carbohydrate was only 38 g. She then kept free from glycosuria with a normal blood-sugar and without any insulin on less carbohydrate.

The interesting features here are the prompt improvement on diet and the failure of insulin to improve the situation as to carbohydrate tolerance. But as the blood-sugar began to rise again and reached 0·19 per cent. I have resumed insulin.

Chronic Cases.

The effect of insulin is not nearly so striking in the chronic cases. I have tried it on several of my original cases which have been treated by alimentary rest since 1915 or 1916, and although some degree of benefit has undoubtedly resulted, I have, on the whole, been rather disappointed. The following case

is worth considering because, owing to the skilled and devoted attention the patient receives, the data are specially full, though I do not propose to burden you with the details. He is now about 60 and retired from his profession about 15 years ago on account of diabetes. Just ten years ago I saw him on the verge of coma. On the somewhat unsystematic methods of alimentary rest we were then experimenting with he improved very much, and until the introduction of insulin he remained in a stationary condition on a very restricted diet, although on one occasion an attack of influenza nearly sent him into coma again. He was one of the earliest cases to be treated with insulin in this country, but his improvement has not been very striking. The difficulty is that if his blood-sugar is brought down even to 0·15 per cent. he has hypoglycæmic symptoms, while at this level of blood-sugar he can tolerate only a very limited diet without a return of glycosuria. It seems to me that only those cases of severe diabetes survive for anything like this length of time which can adjust themselves to bear a certain degree of hyperglycæmia, and if this is now reduced they become uncomfortable at once. But if the hyperglycæmia continues it follows of necessity that no striking improvement can occur.

Another difficulty may occur with insulin treatment if the weight is allowed to increase quickly. Metabolism bears a definite relation to the total body-weight, and, as this goes up, the whole of the metabolic processes are increased. So that the chances of recurrent glycosuria are thereby enhanced. We should not be too eager to increase the weight rapidly.

FAT METABOLISM IN DIABETES.

The following case illustrates some points in connexion with the difficult question of lipæmia in diabetes. A man of 40, who had been known to be suffering from glycosuria for about two years, was admitted to St. Bartholomew's Hospital under my care with 2 per cent. of sugar and definite ketosis. He did not become free from sugar on a fast or on going up the ladder. He showed marked lipæmia and a blood-sugar of 0·263 per cent. Ten units of insulin were given daily, which rendered him free from sugar, but as he began to get œdematous his diet was increased and a second dose of insulin, 5 units, was given daily. On this his blood-sugar was 0·117 per cent., but the lipæmia increased; and he began to sweat after insulin was given, the first indication, in my experience, of hypoglycæmia. His insulin was therefore reduced to two doses of 5 units, the vegetables containing 5 per cent. of carbohydrate were increased, and the fat in the diet was reduced as much as possible. His blood-sugar rose to 0·17 per cent. and lipæmia was still present. I now decided to increase both the insulin and his carbohydrates to see whether in this way we could get him free from lipæmia. On reaching a calorie value of 1818, including 45 g. of carbohydrate as well as fat, we abolished lipæmia and kept the blood-sugar at 0·137 per cent. with two daily doses of 10 units of insulin. On this he was free from glycosuria and acetonuria. The conclusion would appear to be that lipæmia is best treated by increasing both the carbohydrate diet and the dosage of insulin. His general condition decidedly improved on this line of treatment. T. H. Oliver says:

> "Fat properly absorbed into the tissues appears to increase the storage of carbohydrates; if not so absorbed, or if mobilised by calcium, the storage is interfered with. Possibly improper storage of the fat may account for the tendency of a high fat diet to produce glycosuria in some cases of diabetes. It is noticeable that practically all conditions which lead to a hyperglycæmia lead to a lipæmia as well; this may be attributed to diminished oxidation."

At any rate, we may agree that this shows how close are the links between the metabolism of the two foodstuffs, and that diabetes is not merely a disturbance of carbohydrate metabolism. My case would further show that it is sometimes easier to control lipæmia if the amount of carbohydrate metabolised is deliberately increased by adding starch to the diet and giving larger doses of insulin than by restricting the fat in the diet.

It has, of course, long been recognised that it is the disturbance of fat metabolism which ultimately leads to coma. It was the recognition by Hurtley that much of the toxic diacetic acid came not from the fat of the tissues but from the fat of the food, which led in this country to the introduction of alimentary rest by Graham. In America Allen reached the same conclusion as to treatment by a different route. Since this has been appreciated coma has become rarer, though sometimes it remained inevitable in cases of "total" diabetes, or in the presence of intercurrent infection, particularly as we were still without a method of controlling the hyperglycæmia effectively, which in itself further disturbs fat metabolism.

DIABETIC COMA.

Now that we have in insulin a method both of controlling hyperglycæmia and improving fat metabolism, our hands have been greatly strengthened in dealing with diabetic coma. A striking success was achieved in such a case under my care with Dr. Graham's aid. A man was admitted to St. Bartholomew's Hospital in deep coma. His blood-sugar was 0·39 per cent., there was marked lipæmia, and his alveolar CO_2 only 0·9 per cent. His bowels were cleared out with an enema of magnesium sulphate and 30 units of insulin were given at once. In the course of 24 hours 110 units were given and the blood-sugar fell to 0·23 per cent. Two days later air-hunger returned and his blood-sugar rose despite 140 units of insulin to 0·36 per cent. He complained of pain in the right ear and the drum was found to be bulging. It was punctured and pus escaped. After that he steadily improved, and we succeeded in keeping his blood-sugar normal on two doses of insulin daily, one of 20 and the other of 10 units. He remained free from sugar for a month before discharge from hospital, although his calorie intake was worked up to 2365. I recently heard that he is still free from sugar and diacetic acid, although it is six months ago since he was admitted. This case illustrates very well the powerful aid insulin renders in coma, but also the great influence focal sepsis has in antagonising it, for the blood-sugar rose to 0·36 per cent. in the presence of otitis media in spite of 140 units of insulin.

I cannot hope to have dealt with all the aspects of a problem which is now changing from day to day, but it is only by pooling our common experience that advance can be made. And once again I would like to urge that it is resting hyperglycæmia that matters, for it establishes a vicious circle of serious import.

An Address
ON
INSULIN IN GENERAL PRACTICE.

Abstract of a Paper read before the Hampstead Medical Society on Dec. 6th, 1923,

BY GEORGE GRAHAM, M.D. CAMB., F.R.C.P. LOND.,

FIRST ASSISTANT IN MEDICAL CLINIC, ST. BARTHOLOMEW'S HOSPITAL; PHYSICIAN TO ROYAL NORTHERN HOSPITAL.

INSULIN can be used in general practice with great advantage to the patient and without any danger, provided that certain precautions are observed. There has naturally been some difference of opinion as to the best method of using insulin. Banting[1] and the Toronto school, and Allen[2] in U.S.A., Graham and Harris,[3] Spriggs,[4] Poulton,[5] MacLean[6] in this country all argue that the aim of the physician should be not only to render the urine sugar-free but also to maintain the amount of sugar in the blood within the normal limits of 0·09–0·12. Joslin[7] aims at keeping the urine sugar-free, but Geyelin,[8] Woodyat,[9] Wilder,[10] all think that it does not matter if the patient does pass sugar and has a high blood-sugar just before the insulin injection.

IDEAL OF TREATMENT.

My experience during the last six months, after watching the progress of the patients who are having insulin, has confirmed me in my opinion that it is essential to maintain the same ideal as we have always had—namely, to keep the blood-sugar within normal limits if the patient is to continue to progress satisfactorily. The first patient treated in the medical clinic at St. Bartholomew's Hospital illustrates very well many points and difficulties in the use of insulin. The patient, a man, aged 26, had been ill for three years, and had been very near coma about four weeks before admission. In spite of two starvation days, two egg and vegetable days, and two more starvation days, he continued to pass sugar, and the blood-sugar remained at 0·20 per cent. When the diet was increased to protein 53·2 g., fat 109·5 g., and 16 g. of

FIG. 1.

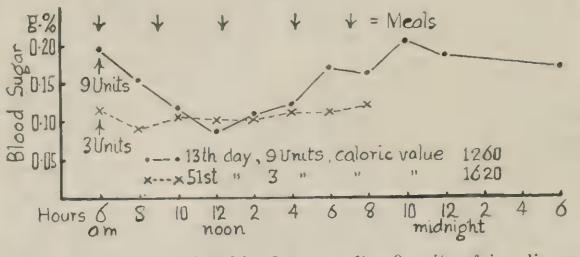


Chart to illustrate fall of blood-sugar after 9 units of insulin on the 13th day of treatment and after 3 units on the 51st. (From "Pathology and Treatment of Diabetes Mellitus," Oxford Medical Publications.)

sugar in the form of vegetables, total calorie value 1260, the blood-sugar varied between 0·23–0·25 per cent. and the sugar output from 25–33 g. Insulin was given in gradually increasing doses up to 10 units, and by the thirteenth day the urine only contained sugar in the period immediately before the insulin injection, and the blood-sugar at that time was 0·20 per cent. The blood-sugar was estimated throughout the day at two-hourly intervals, and the curve (see Fig. 1) is typical of the action of insulin, and should be remembered whenever the action of insulin is considered. The maximum lowering of the blood-sugar in this case occurred at the sixth hour after the injection (although at may be as early as the third hour) began to pass off at the tenth hour, and was completely over at the sixteenth hour. The diet and dose of insulin were kept constant, and the morning blood-sugar gradually diminished to within normal limits, so that by the fifty-first day, after only 3 units of insulin, it was below 0·11 per cent. for 14 hours. The patient's sugar-tolerance continued to improve, and on the seventy-third day, when no insulin was given, he was able to eat 40 g. of bread without passing any sugar in the urine, though the shape of the blood-sugar curve was abnormal. Now, ten months after the treatment was started, he has gained 1½ stone in weight, and feels very well. He has usually had a normal blood-sugar 24 hours after the last insulin injection, but when he had a cold and sore-throat the blood-sugar was 0·19 per cent. The diet was therefore reduced from 1800 to 1400 calories, the bread was stopped, and the insulin increased to 20 units. Two weeks later the blood-sugar was again normal, and the insulin was reduced to 15 units, and the diet slowly increased again.

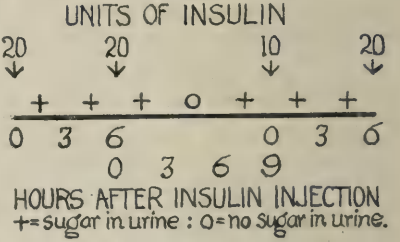
Blood-sugar Observations Not Essential.

In learning how to use insulin it was necessary to make many observations of the blood-sugar, but these are now unnecessary, provided that the urinary sugar is watched and the effect of the insulin observed. But before starting treatment it is important to discover and treat any other sources of infection, such as boils, pyorrhœa, or any septic foci. Tuberculosis of the lungs should be sought for most carefully, as it is a common complication in long-standing cases. It is a good plan to start the treatment with an attempt to get the urine sugar-free by dietetic measures. It is wiser to keep the patient in bed, but it is not necessary to give a long period of starvation, such as Allen originally used, but a one or two days' fast, followed by a gradual increase in the diet to three eggs, 2 oz. of meat, 2 oz. of bacon, 2 oz. of ham, 1½ oz. of butter, 1 oz. of cream, 12 oz. of cooked green vegetables, and 4 oz. of uncooked vegetables. This makes a total of 57·7 g. protein, 118 g. fat, 16 g. of sugar in the form of vegetable, with a calorie value of 1358. This amount of food is sufficient for an adult of 10 st. 5 lb., and is rather less than 1 g. of protein per kilo (½ g. per pound) and 21 calories per kilo (10·5 per pound). If the patient weighs more or less than 10 st. 5 lb. the diet must be increased or decreased, keeping the proportion of grammes of protein and calories per pound about the same.

Value of a Standard Diet.

It is, I think, a great advantage to have a standard diet, such as the ladder diet, as it is very simple for the patients to carry out, and the necessary deductions or additions, according to the weight of the patient, are very easily made. The correct diet for children is much more difficult to adjust. The basal heat production should be ascertained from the tables of Benedict and Talbot, or from Wilder's nomograph.[11] An addition of 20 per cent. is made to allow for the effect of exercise, &c., and the diet worked out, allowing 1·0–1·5 g. of protein per kilo (0·5–0·75 g. per pound of body-weight). If on this diet the patient continues to pass sugar, 10 units of insulin should be injected before breakfast, and the urine collected in approximately three-hour periods throughout the day. The urine should be tested qualitatively for sugar by Fehling or Benedict's test. A nurse or the patient can soon learn to do these tests, and keep a three-hourly chart of them for the doctor. If the patient was passing sugar the blood-sugar was over 0·19 per cent., and the urine passed in the first three hours will certainly contain sugar. If,

FIG. 2.



Three-hourly chart.

however, the blood-sugar has decreased, as in Fig. 1, below 0·19 per cent., there will be no sugar in the urine from three to six hours after the insulin. If, however, the dose of insulin was not big enough, the blood-sugar will not fall below 0·19 per cent., and sugar will be present in every specimen. In this case, after three days, the dose of insulin should be increased to 15 units, and if the specimen of urine still contains sugar, the dose must be increased to 20 units after another three days. If the dose of insulin is sufficient to lower the blood-sugar below 0·19 per cent., the urine from three to six hours will be sugar-free; but that from six to nine hours will contain sugar, if the blood-sugar has risen above 0·19 per cent. If this occurs the dose of insulin should be kept steady, and the urine of the period from six to nine hours tested daily. If the dose of insulin is adequate the sugar-tolerance of the patient will improve, and the urine of the period six to nine hours will become sugar-free. If it does not, then the dose of insulin must be increased. If the urine for six to nine hours becomes sugar-free, the urine from nine to 12 hours must be tested, and this in turn will become sugar-free. This process must be continued until the urine is sugar-free throughout the 24 hours.

Watching for Overdosage.

At this stage it is a great advantage to know what the blood-sugar is, but if this is not possible it can be gauged by watching the effect of the insulin. An adult who has a normal blood-sugar cannot take more than 10–12 units on this diet without having mild symptoms of overdosage. It is not necessary to give sugar for the mild symptoms like sweating or inertia as a hot drink, an egg or a tomato will at once relieve the patient. If the method described here is used there should be no serious symptoms, but it is well to warn the patient or nurse that adrenalin, 1 in 1000, ℥ xv., subcutaneously will at once relieve the symptoms, or two to four lumps of sugar by mouth.

If no symptoms of overdosage occur after 20 units it is probable that the blood-sugar is above 0·14 per cent., and the insulin should be kept steady at 20 units until symptoms are produced, and should then be decreased by 2 units at a time, watching the patient carefully. Experience has shown that the symptoms do not always tally with the blood-sugar, and it is a great advantage to know exactly how high the blood-sugar is before the insulin is given. When the blood-sugar is normal, and only 10 or 15 units are required, the diet can be gradually increased, but it is wiser to add to the protein and fat ration in preference to the carbohydrate, so as to give the β cells of the islands of Langerhans as good a rest as possible. The calorie value may be raised to 1800 or 2000, and the protein ration to 1·5 g. per kilo (0·75 g. per pound) of body-weight.

Procedure in Mild Cases.

The above procedure is necessary for the patient with severe diabetes, who continues to pass sugar even after severe dietetic restrictions. Most patients cease to pass sugar on the diet suggested, but the blood-sugar may still be high, 0·17 per cent., and it is an advantage to know the blood-sugar at this stage. If this is not possible, a dose of 10 units should be given each day, and the effect of increasing the dose to 12 or 14 units watched. If, after 14 units, no symptoms of overdosage such as sweating or a feeling of inertia are observed, the blood-sugar is probably above 0·14 per cent. The dose should be kept at 14 units until symptoms appear, and then decreased to 12 or 10 units. When this stage has been reached the diet should be kept constant for two to four weeks before the addition of the extra protein and fat. Later on ½ oz. of bread may be given after the insulin injection. If this is tolerated the bread can be increased by ½ oz. portions, first at the insulin meal and later on at other meals. The exact correspondence between sugar and insulin is not quite certain, but 1 unit is sufficient for 1–1·5 g. of sugar. This ratio is important if it is desired to add bread together with the equivalent amount of insulin. Although it is sometimes necessary to do this, I do not think that it is really good practice. The insulin requirements of the full ladder diet with 16 g. sugar are not yet known, but may be regarded as 50 units $+x$ units. If a patient is being given 10 or 20 units, it is clear that the β cells of the patient will only have to produce 30 or 40 units $+x$ units. It is this relief of the β cells by the correct use of insulin which is the important point to bear in mind. Even if the patient can also eat 1 oz. of bread the insulin requirements will be 50 units $+$ (14 or 8) units $+x$ units. The correct way is still to think that the β cells are being spared the production of 10 or 20 units of insulin.

If the patient continues to pass sugar after 20 units in the morning, he needs more insulin, but it is wiser to treat such a patient either in a hospital or nursing home, or with two competent nurses, in order to avoid the danger of overdosage, since the dose may have to be increased to 25 units in the morning and 20 units at night.

Treatment of Coma.

The condition of coma requires prompt treatment with large doses of insulin. There is usually already an excess of sugar in the blood, as it has varied from 0·30–0·39–0·73 per cent. in my last three cases, so that it is usually safe to give 30 units of insulin. But a dose of 50 g. (2 oz.) of dextrose by mouth or by œsophageal tube cannot do any harm. If the patient has not shown any signs of returning consciousness in three hours another 20 units should be given. The dosage can be gauged by testing the urine every three hours. If sugar is still present from three to six hours after the injection it is safe to give another 20 units. If there is no sugar in this specimen no insulin should be given until sugar reappears, and then only 10 units. In this way the dose of insulin can be regulated with safety. It is better to give water only for two days, and then start on the gradual ascent of the ladder diet. It is most important to search for any other sign of infection, as in four out of five cases of coma at St. Bartholomew's Hospital an acute infection has been found. If this is the case, the calorie value should be rapidly increased, and the insulin dosage regulated accordingly.

OPERATIONS AND MINOR AILMENTS.

Patients suffering from such conditions as carbuncles, gangrene of the leg, appendicitis, &c., should be prepared for operation by treatment with insulin. If the operation can be delayed for a few days it is better to get the urine sugar free by fasting and insulin, but if the operation is urgent a dose of 30 units of insulin and 50 g. (2 oz.) of dextrose should be given immediately before the operation. Afterwards the diet for some days should consist of the ordinary diet which is given to this type of case, milk, &c. The sugar output is watched by testing each specimen of urine and giving insulin on the same system as that described in the treatment of coma. The anæsthetic should be gas and oxygen by preference, but if this is not sufficient a little ether may be given as well. Local or spinal anæsthetics are very good.

The minor ailments, such as "colds in the head," tonsillitis, &c., require careful treatment. They should always be taken seriously, and the patient should go to bed. It is better to reduce the diet by one-third and add another 5 units to the dose of insulin. When the patient is better the food can be increased again. Whether the infection acts directly on the β cells, or indirectly by causing a demand for a bigger output of insulin than they can produce, is unknown. The minor infections are largely responsible for the decline in sugar tolerance which was so disappointing in the old days. One important point in the treatment is to relieve the constipation which is nearly always present, and especially when the patient is comatose.

From this description it is clear that the use of insulin does not free the patient from dietary restrictions, but the improvement of the clinical condition is so striking that the patients are much more willing to put up with these than they were before insulin was introduced.

A CASE OF HEART-BLOCK PRESENTING SOME UNUSUAL SIGNS.

BY A. J. SCOTT PINCHIN, M.D., M.R.C.P. LOND.,
PHYSICIAN, CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS, VICTORIA PARK;
AND
S. ROODHOUSE GLOYNE, M.D. LEEDS, D.P.H.,
PATHOLOGIST TO THE HOSPITAL.

THE case here described exhibited certain features of clinical and cardiographic interest which seem to merit recording.

A male, aged 20, had pneumonia at 10 years, and doubtful tuberculous peritonitis at 13. Influenza in 1919. Admitted to the City of London Hospital in April, 1920. He was then very anæmic, had a soft systolic mitral bruit, stained sputum, and mild, irregular pyrexia. There were no abnormal signs in the lungs, and the sputum was negative for tubercle bacilli on 11 occasions. Discharged improved, and having gained 7 lb. in weight. Readmitted January, 1921, with hæmoptysis. He was afebrile, with pulse of 110. Sputum was negative as to tubercle bacilli on nine occasions. Hæmoptysis ceased, pulse was reduced to 80, and on discharge he went back to his work. Later developed "faint attacks," though he never completely lost consciousness, and he was admitted to the hospital again in October, 1921. He then complained of fainting attacks, dyspnœa, and palpitation. The heart was normal in size; there was a systolic murmur at apex conducted to axilla. At the base the sounds were normal. The pulse was 84, of fair volume and tension. The lungs were normal, the urine contained a faint trace of albumin. No other abnormalities discovered.

Cardiographic Findings and Course of Case.—Prior to this admission a cardiogram (Fig. 1) had been taken. This showed a slight grade of block, the As-Vs interval being 0·24 seconds. The ventricle responded to supraventricular stimuli, but the form of complex was abnormal, occupying 0·14 seconds. There was slight notching of the downward deflection, and the picture was that of a contraction commencing in the left ventricle. Conclusion: Partial block of the main division of the bundle and also block of the right branch of the bundle. Both Wassermann reaction and blood culture were negative. Blood count showed only a slight degree of anæmia. About a fortnight after admission the pulse-rate suddenly dropped to 36 per minute, and it was evident that complete block was established. The second cardiogram (Fig. 2) showed complete heart-block; the auricle was contracting at the rate of 120 per minute, the ventricle 36 per minute, but whereas in the previous cardiogram the right branch of the bundle was shown to be blocked, in this case it was the left branch which was in default, as evidenced by the direction of the deflections. On Nov. 13th, 1921, the complete block had disappeared, and the appearances of the cardiogram were the same as in Fig. 1. The following day complete block occurred again and remained complete till death. On the 17th, at 8 P.M., the patient felt dizzy and "lost himself" for a second. During the whole of the 18th he felt very "seedy," and the following night he had a bad attack of faintness with slight twitching of the face and limbs, but no convulsion. Lesser attacks occurred frequently. At the apex of the heart the auricular beats could be distinctly felt and seen, and with the stethoscope could be heard as loud regular beats bearing no time relation to the forcible ventricular beat which occurred usually at the rate of about 24 per minute. Occasionally the ventricular beat would stop for a period of 10–12 seconds, the patient's eyes would close, and the succeeding beat would be followed by a deep sigh and reopening of the eyes; there was no twitching. Atropine and sodium salicylate in full doses produced no effect on the heart-rate. Mercury and iodides also failed to produce any effect. Cardiograms showed, on Dec. 24th, complete heart-block with right bundle branch block; on the 28th complete heart-block with left bundle branch block; and on Jan. 8th, 1922, the complete heart-block with right bundle branch block again. On Feb. 2nd the patient's condition continued so distressing that it was determined to try the effect of digitalis in an endeavour to stimulate iodiopathic contractions in the ventricle. He was given 1/240 gr. nativelle twice daily, and on the 11th the auricular rate had fallen to 80–90 from 110–120, whilst the ventricular rate remained unchanged. On the whole the patient felt rather more comfortable and had no attacks. Another cardiogram (Fig. 3) showed that the period between the auricular beats was unequal; some beats were inverted and appeared to arise from an ectopic focus. On the 14th definite coupling appeared and the digitalis was stopped. The patient was quite comfortable and the ectopic beats were effective. Another cardiogram (Fig. 4) showed an auricular rate of 140–150. The auricular complexes were abnormal; in lead 3 they were alternately inverted, the rise in rate to about double suggested the possibility of alternate auricular extra systoles. There was coupling of the ventricular beats; the first beat of the couple, supraventricular, showed right side branch block following an ectopic beat arising in the left side of the ventricle. In lead 1 the second beat of the couple was apparently arising in the interventricular septum. Subsequently the patient had no further faint attacks, he felt more comfortable, but complained of palpitation. The auricular systole was not nearly so forcible, and the sound could be heard faintly over the base of the heart, but not at all at the apex.

FIG. 1.

FIG. 2.

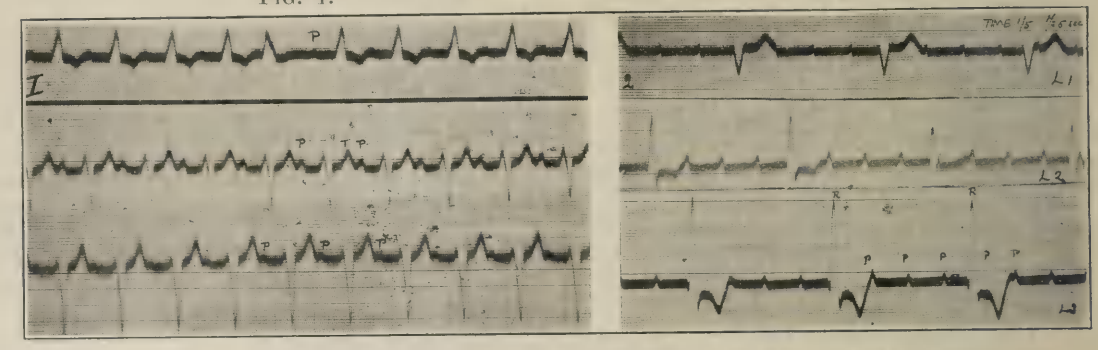

FIG. 1.—Partial block of main division of bundle and block of right branch of bundle.
FIG. 2.—Complete heart-block of left branch of bundle.

On March 7th it was resolved to make a further effort to propagate ectopic beats via the sympathetic system. Half a grain of thyroid extract was given three times daily and gradually increased to two grains. It was stopped on the 18th, the patient complaining of specks in front of his eyes and palpitation. During this time he had short attacks, lasting a few minutes, in which the pulse-rate rose to 60–70, but they distressed him, and we were never able to cardiograph him in one of these periods. As no drugs appeared to have any beneficial effect he was from this date given little in the way of treatment. His condition varied little, there were short periods of slight improvement, but on the whole he went progressively downhill. On August 26th he began to have more faint attacks with slight twitching. Adrenalin was tried, but failed to give any relief, and he died on the 29th in an attack. During the whole illness he never had a convulsive attack.

Post-mortem Examination.—This examination, made on the 30th, showed soft recent adhesions of both pleural sacs with old, tough adhesions at the left base, and much engorgement of both lungs with bronchioles filled with mucus. The liver showed a typical "nutmeg" appearance, and the spleen was hard and fibrotic, with a thickened capsule but no infarcts. The pericardium contained some 5 oz. of clear fluid and the heart weighed 21 oz. The heart muscle was hypertrophied and rather pale in colour. Both auricles were dilated, especially the left, in which the endocardium was thickened. There was also slight thickening of the flaps of the mitral valve, but no lesions were noted in the other valves. There were many yellowish-white patches

of degeneration visible in the myocardium immediately beneath the endocardial lining. These patches were most marked in the interventricular septum (Fig. 5) and presumably involved the bundle of His. Unfortunately it was not possible to cut serial sections of the bundle, but isolated sections of one of these yellowish-white patches in the septum showed typical chronic myocarditis with well-marked patches of new-formed connective tissue with fibroblasts.

FIG. 3.

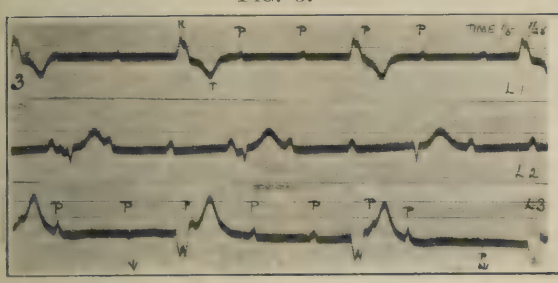

FIG. 4.

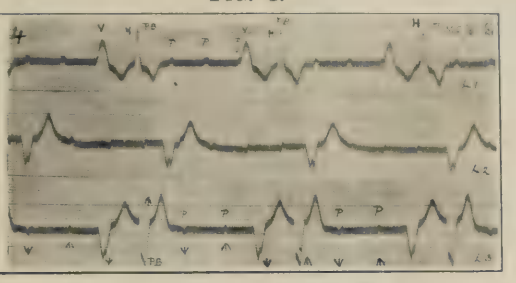

FIG. 3.—Showing unequal periods between auricular beats; some of the latter were inverted, and apparently arose from an ectopic focus.

FIG. 4.—Alternately inverted auricular complexes in lead 3, the rise in rate suggesting possibility of alternate auricular extra-systoles. There was coupling of ventricular beats; the first (supraventricular) beat of the couple showed right-side branch block, following an ectopic beat arising in left side of ventricle. In lead 1 the second beat of the couple apparently arose in the interventricular septum.

Interesting Points in the Case.

The points of special interest in this case are as follows:—

1. The mode of onset, short history, and complete invalidity of the patient. During the whole illness he had to be kept flat, and much of the time had the foot of his bed raised.

2. The very forcible character of the auricular beat at the commencement. In most cases the auricular beat can be heard at the base, but it must be very rare to hear it so plainly at the apex, and still more so to be able to see and feel it in that situation.

3. From the fact that the patient had a bundle branch lesion at the time when there was only delay in the main branch of the bundle we may reasonably assume that the picture is that of a branch block and not that of an ectopic beat arising on one or other side of the ventricle. If the first cardiogram (Fig. 1) had not been seen it would be hard to prove that this latter was not the true reading. It would seem that we must assume two lesions of the bundle system, the upper rapidly involved the main bundle, the lower probably situated near the fork of the branch, so that the extension or recession of the inflammatory area at one time involved one side of the bundle and at another time the other. A simultaneous involvement of both branches may have been the cause of death.

4. The slowing of the auricular rate under the influence of digitalis and the alteration of the auricular complexes as evidenced by inverted P waves in Fig. 3. (Direction of P waves marked in cardiogram by a broad arrow.)

5. The increase of auricular rate 90–130 under the further influence of digitalis. Possibly if the digitalis had been continued the auricle would have proceeded to fibrillation.

6. The notching and diphasic appearance of the P wave whilst under digitalis, which is not to be noted at any other time.

7. The picture of the ventricular ectopic beats stimulated by digitalis. In nearly all cases the idiopathic ventricular beat arises on the same side of the heart as the contraction starts—i.e., the side away from the blocked branch. The normal appearance of the idiopathic beats in lead 1 in association with this double block supports Hewlett's proposition (*Heart*, 1921, vol. ix., 1) that such complexes are an indication of an idiopathic ventricular beat arising in the ventricular septum.

FIG. 5.

Heart of the case described, showing light patches of degeneration in myocardium immediately beneath endocardial lining, being most marked in the interventricular septum, and presumably involving the bundle of His.

Since this article was written an interesting paper on the Action of the Auricle during Periods of Ventricular Silence has been published by Wiltshire.[1] His graphs show gradual failure of the auricle, ectopic auricular beats, and periods of auricular flutter. Other cases have been published showing auricular fibrillation as a sequel to complete block. In the case recorded the auricular beat remained regular and constant except as a result of the administration of digitalis, when slowing of the rhythm and ectopic beats gradually appeared. It would appear that the piling up of stimuli unable to pass the bundle is one factor which may produce alterations in the auricular rhythm, flutter, or fibrillation.

We have to thank our colleagues Dr. W. J. Hadley for access to the case and permission to publish these notes, and Dr. F. G. Chandler for use of the out-patient notes.

THE CRITERIA OF CURE IN TUBERCULOSIS OF THE GUINEA-PIG.

WITH SPECIAL REFERENCE TO DIAPLYTE ANTIGENS.*

BY E. H. KETTLE, M.D. LOND.,
PATHOLOGIST, ST. MARY'S HOSPITAL.

THERE is evidence to show that the majority of individuals possess a good deal of natural immunity against the tubercle bacillus, or are able to elaborate, should necessity arise, sufficient protective substances to overcome moderate degrees of infection. But, on the other hand, when once tuberculosis becomes established the mortality-rate is very high. The treatment of the disease is still one of the most pressing problems in practical medicine, for while no therapeutic agent having a specific action on the bacillus has yet been discovered, immunological methods of treatment have met with only partial success, though since the days of Koch's original tuberculin many forms of tubercle antigen have been suggested.

The literature of tuberculosis is full of the records of experiments dealing with the treatment of tuberculous animals, chiefly guinea-pigs. For the most part the materials employed have not proved satisfactory, but some authors report astonishingly good results. Takeoka,[1] treating tuberculised rabbits and guinea-pigs with taurin, found that they gained in weight as compared with control animals, lived longer, and upon examination presented evidence of arrest or cure of the disease. Koga,[2] working with preparations of copper, also obtained good results, and many other similar experiments could be quoted. It is significant, however, that none of these remedies have found permanent favour in the treatment of human tuberculosis, and it is therefore necessary to scrutinise very carefully the experimental evidence upon which their alleged value is based.

Two assumptions seem to underlie all these experiments: (1) That all guinea-pigs react in the same way to the tubercle bacillus, and (2) that fibrosis, or healing, of local lesions indicate with certainty the cure of the individual. Both these assumptions are false, as I shall hope to show, and the failure to recognise this is sufficient to explain the disagreement between the clinical and the experimental results. (1) The reports of the Royal Commission on Tuberculosis[3] make it clear that individual guinea-pigs differ among themselves in their reaction to *B. tuberculosis*. In one experiment ten guinea-pigs, inoculated with a strain of human tubercle bacilli, died of tuberculosis in periods ranging from 46–151 days. In another, 30 animals inoculated with a slightly virulent human bacillus died in periods ranging from 39–244 days. (2) A knowledge of human pathology throws doubt on the second assumption, for it is a commonplace of the post-mortem room to find fibrosed and encapsuled caseous tuberculous lesions in the lungs or other organs associated with an acute local or generalised exacerbation of the disease, though a careful microscopic examination of such lesions often reveals that an active though indolent form of tuberculosis is present at some part, usually the periphery, of the "healed" focus. These broad facts of human pathology are generally recognised, but pathologists are less well informed about the actual course of tuberculosis in guinea-pigs. These animals are usually only infected experimentally for purposes of diagnosis, and not with the object of studying the actual progress of the disease in them. Therefore, if they are to be used as subjects for the investigation of the therapeutics of tuberculosis, it is essential to establish standards by which it is possible to control the results; for if we have not accurate knowledge of the actual progress of the infection in the normal animal, it is impossible to estimate the value of any particular form of treatment.

The most recent remedy suggested for the treatment of tuberculosis is the defatted or "diaplyte" antigen described by Prof. G. Dreyer.[4] Injected into rabbits, this antigen caused the appearance of various immune substances in the blood of the animals, while used therapeutically on tuberculous guinea-pigs and rabbits it gave encouraging results. In the author's words: "Treatment with the 'defatted' antigen brings about a definite improvement, both general and local, in animals infected with *B. tuberculosis*. Additional evidence for this view is given by the guinea-pig No. 27 which died, for its organs show what seems indubitably to be a healing of tuberculous lesions."

Although the scope of Dreyer's paper extends much beyond the limits of the treatment of tuberculosis, it was this aspect of his work which chiefly aroused interest, and obviously demanded immediate consideration. Now, the final test of any therapeutic measure must be its effect upon the health of the average patient. No demonstration that, by all the rules, it ought to cure the patient is of any avail unless, in fact, it does; for, as Calmette[5] says: "Antibodies cannot be regarded as the essential element in the defence against tuberculous infection." Therefore that part of Dreyer's paper which deals with the actual treatment of tuberculous animals transcends in importance the larger, serological part, interesting though this is, and I do not propose to discuss either the general immunological considerations raised by him or the intrinsic merits of the diaplyte antigen.

The Evidence for the Value of the Diaplyte Antigen.

It is, of course, notoriously difficult to estimate the value of a therapeutic agent, for the control of the various factors in the experiment may be quite impossible, and it would be unsafe and unjust to condemn any form of treatment on clinical evidence alone without giving it an extended and sympathetic trial. On the other hand, we may justifiably demand that there should be reasonable grounds for believing the treatment to be efficacious before we are asked seriously to consider it. A critical examination of Dreyer's paper provides really little evidence of the value of his antigen as a curative agent. The rabbit experiments scarcely need to be considered, for the details given are much too meagre to enable the reader to form a definite opinion of the value of the treatment, and, further, that animal which showed the most severe lesions was chosen to be the control.

Duration of Life.—The four guinea-pigs used were inoculated with a culture of low virulence which, it is stated, usually killed the animals in from four to ten months with generalised tuberculosis. Two, Nos. 27 and 28, were the survivors of a batch inoculated on April 20th, 1922, while No. 26 was probably infected about this date. No. 4 was infected on June 15th, 1922. One animal died 50 weeks after infection, but the others were alive on May 18th, 1923, and had therefore lived longer than the general run of animals infected with this particular strain of bacillus; though not, so far as we know, longer than it is possible for untreated animals infected with this particular strain to survive, especially if we suppose, as it is not unreasonable to do, that they were specially well cared for. In these experiments improvement was noted in the condition of the local lesions, and the palpable glands diminished in size, but this is not conclusive, for it may happen in untreated animals which survive for any time, and is not an indication of actual cure.

Weight.—Dreyer lays stress on the weight of the animals as an indication of their general health. "In an animal of this species, the weight is the best indication of the general condition of health." One of the animals became pregnant, and its weight is not recorded. Of the others, No. 4 weighed 630 g. at the beginning of treatment, and 946 g. after 20 weeks, the end of the period recorded, an increase of 50 per

* Being a paper read at the Pathological Society of Great Britain and Ireland on Jan. 4th. This work was done under a research grant from the Medical Research Council.

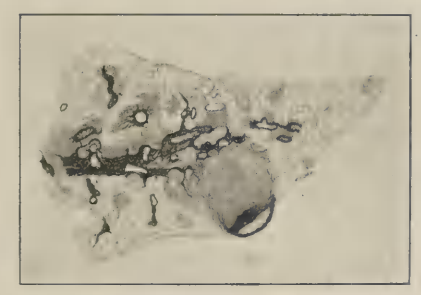

FIG. 4.—Low-power drawing of a section of the lung from guinea-pig No. 10, 5A. Showing fibro-caseous tuberculosis.

FIG. 3.—Higher magnification of Fig. 2 including part of the wall of the large cyst. Showing extreme fibrosis with destruction of liver tissue and dilatation of bile-ducts. There is some new bile-duct formation which is often a prominent feature in these livers.

cent. No. 26 weighed 813 g. at the beginning of the 16 weeks' treatment, and 840 g. at the end, an increase of 3 per cent.; while No. 28 lost 34 g., or 6 per cent. of its weight in the same time. Quite as favourable results as these may be seen in untreated animals. Finally, one of the animals died, and was subjected to careful naked-eye and microscopical examination. It showed lesions which were interpreted as indicating a tendency to healing. But no description of similar investigations of untreated guinea-pigs are given for comparison, and the results which I have obtained lead me to believe that these findings may occur equally well in untreated tuberculised animals.

Object of Present Experiments.

The author's authority, however, combined with the support of other workers, gave reason to believe that a more potent immunological agent was now available, and my experiments were undertaken with the object of studying the differences in the tissue reactions between treated and untreated animals. I was not hopeful of actually curing tuberculous guinea-pigs, because the experiences of vaccine therapy suggest that dosage is the all-important factor, and I did not expect to be able to regulate the treatment successfully except after a considerable period of trial and error; but I hoped to produce such alterations in the tissue reactions in the animals, possibly in an unfavourable direction, as might be a help to me in the line of work upon which I was engaged. My experiments have not hitherto been successful in this respect, but they have brought out very clearly the need for a radical change in the generally accepted standards by which failure or success of therapeutic experiments on tuberculous guinea-pigs are judged.

Turning to the actual experiments on which these conclusions are based, in the first two, 5A and 6A, I used a strain of human tubercle bacilli given me by Dr. W. E. Gye, and the antigen employed was No. 58, given me by Captain S. R. Douglas, who himself had received it from Dreyer. Experiment 11A was carried out with bacillary emulsion and diaplyte antigen prepared in the Inoculation Department of St. Mary's Hospital, and the animals were infected with the "Lyons" strain of human bacilli obtained from the same source. The first experiment was completed, the second far advanced, when Captain Douglas, who in the meantime had himself been working with antigen 58, informed me that he had come to the conclusion that it was not an entirely satisfactory sample. As tests of the value of the antigen in treatment these experiments, therefore, do not carry any particular weight, but as I have explained, I should not in any case be prepared to pronounce judgment on any therapeutic agent without a much more prolonged trial, and I am quite content to regard all the animals in these two experiments as controls.

General Plan of Experiments.

The general plan of the experiments was as follows. The guinea-pigs were inoculated in the right flank with a fine suspension of tubercle bacilli in normal saline. Care was taken to ensure that the suspension was uniform, so that approximately the same dose was administered to all the animals in each particular experiment, but no attempt was made to determine the actual number of bacilli introduced. Animals of varying weight were chosen purposely, so as to compensate as far as possible for the lack of absolute knowledge of the appropriate dose to be administered. In each experiment the animals were divided into approximately equal batches, one of which served as the control. The treated animals received at intervals of usually a week, subcutaneously into the left flank, a dose of antigen corresponding roughly in amount to the dose used by Dreyer in his experiments. For the most part, the animals have been allowed to die naturally, but some were killed, either because they were obviously very ill or for histological purposes. The animals were weighed, and their weight was charted, usually at weekly intervals. Careful post-mortem examinations were made in every case, and, as a routine, the local lesions, the iliac, periportal and tracheal glands, the livers, spleens, and lungs were microscoped; other tissues and glands were cut where it seemed advisable. The animals invariably developed large local lesions which ulcerated after three or four weeks and discharged caseous material. Only in one or two cases did these ulcers completely heal, though occasionally they diminished to the size of a millimetre or so. Even the healed ones broke down again before death occurred, and the most usual lesion was a dry granulating area, sometimes covered by a scab.

Inasmuch as I was merely concerned with the study of the tuberculous lesions, I have made no general bacteriological examination of the animals, and it is quite possible that many of them died of intercurrent infection; indeed, this is obviously what happened in the early deaths occurring in Experiments 6A and 11A.† But every guinea-pig infected with living tubercle bacilli presented progressive tuberculosis post mortem. Usually the post-mortem findings had a monotonous sameness. The iliac, periportal, and tracheal glands were invariably affected, as were often the left inguinal, the right axillary, and the cervical glands. The left axillary glands were less often involved. The lungs, livers, and spleens were always affected, though to a varying degree. Great enlargement of the liver and spleen with massive infarction were very general findings. It is hoped that the charts of the experiments appended are sufficiently self-explanatory as to make detached description unnecessary, and only points of particular interest will be dealt with.

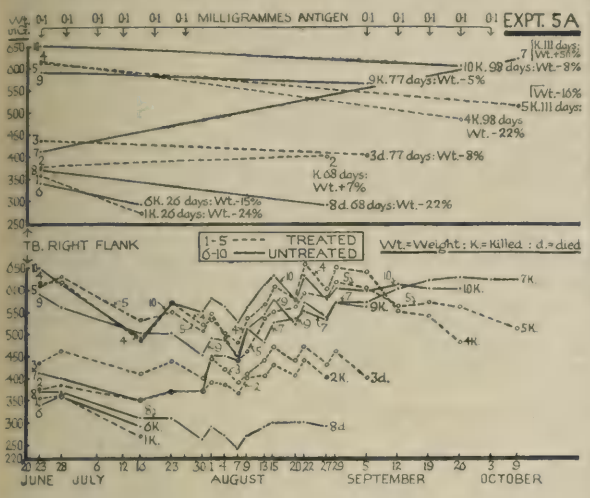
Details of Experiments.

Expt. 1 (5a) (Chart 1).—Ten guinea-pigs were inoculated in the right flank with tubercle bacilli, and five of them (Nos. 1–5) were treated with weekly injections of antigen into the left flank; Nos. 6–10 were controls. During the experiment all the animals lost weight except two; No. 2, a treated animal killed 68 days after injection, gained 7 per cent. of its body-weight, while No. 7, which was untreated, had gained 50 per cent. of its weight when it was killed, 111 days after injection. In the early weeks of the experiment all the animals lost weight. This period coincided with a spell of very hot weather, but the main cause of the loss of weight was undoubtedly imperfect feeding. This is well brought out on the chart during August, when the weights were taken on Mondays and Wednesdays. Invariably there was a fall in the weights on Monday, due to lack of care during the week end, but this was made up by the Wednesday. All of the first six guinea-pigs dying or killed showed progressive tuberculosis. The disease was most advanced in No. 8, which was always a weakly animal, but except for some minor variations in the extent to which the different organs were involved, there is little or nothing to choose between the rest. The chief interest centres in Nos. 4 and 5 (treated) and 7 and 10 (untreated); 4 and 5 both lost weight rapidly towards the end, and when killed were found to be extremely emaciated. In No. 4 the lymph nodes throughout the body were very small and hard, the spleen was shrivelled and scarred, and the liver was firm on section and apparently cirrhotic. The lungs were studded with rather small fibrous tubercles.

In No. 5 the appearances were much the same, but the spleen was a trifle larger; the liver contained a small cyst, and in the lungs the infection was more advanced and there was a condition of active sero-fibrinous pleurisy at the left base. Microscopically both these animals showed a very chronic form of tuberculosis with fibrosis and scarring. This is particularly well seen in the lymph glands, though even here small cellular foci are plentiful among the organised fibrous tissue, and small caseous areas are occasionally to be seen. The spleen shows fibrosis with areas of calcification, but active cellular foci are also present, and in these organs, as in the lymph glands, bacilli can easily be found. The hepatic lesions in both animals are very similar, consisting of a coarse portal cirrhosis, with active cellular tuberculous foci. The fibrosis obviously represents the healing stage of a tuberculous inflammation, and is so far advanced as to cause obstruction of some of the ducts, with cystic dilatation of their lumina behind the obstruction. The cyst in the liver of No. 5 is such a dilated bile-duct, but its wall is

† Interesting modes of death which have been encountered are hæmorrhage from an acute gastric ulcer, 6A/16 and 11A/5; and rupture of vessels of enlarged spleen, usually caused by holding animal for inoculation.

largely formed of granulation tissue, containing many tubercle bacilli. Scanty bacilli can also be found in the lesions elsewhere in this liver and in that of No. 4. The lungs in both animals show advanced tuberculosis. Often the lesions are cellular and there is much fibrosis, but there are also large caseous areas. In many parts there are

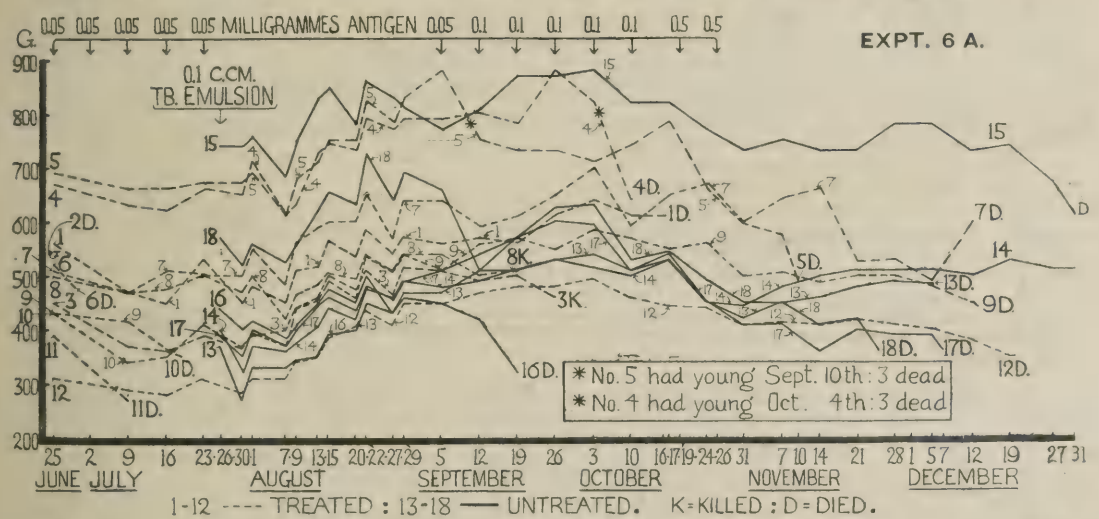


numerous bacilli and at the base of the lung in No. 5 there are enormous numbers of them. In both animals the local lesions were ulcerated, but scarred and fibrous, though tubercles could be made out at the periphery, and the microscopic preparations correspond with these appearances. There is in these animals, then, definite evidence of healing. The local lesions show retrogression and repair, and in other organs it is clear that a much more active and extensive tuberculosis must at one time have been present. Healing in one part, however, is associated with active progress of the disease elsewhere, as is especially well seen in No. 5.

Even more interesting are the control animals, Nos. 7 and 10. In both these the lymphatic glands throughout the body were very large but intensely fibrous, and though bacilli can be found in them they are scanty, and the histology is that of an inflammatory lesion in the healing or fibrosing stage (Fig. 1). In No. 7, which was a well-nourished animal, the lesions in the liver, spleen, and lungs are very similar to those in No. 4, the only practical difference between the two being the much greater size of the lymph nodes in No. 7. In No. 10, however, the fibrosis of the liver noted in Nos. 4 and 5 had proceeded to a much more advanced stage. The liver was considerably increased in size and in its substance and projecting from its surface were numerous cysts (Figs. 2 and 3), containing bile-stained material or clear fluid. Rupture of one or more of these cysts had given rise to a condition of diffuse plastic peritonitis. These cysts are retention cysts of bile-ducts due to the constriction of contracting fibrous tissue. The process is exactly similar to that noted in No. 5, though much more advanced, but I have not found active tuberculosis in any of the cysts in this liver, nor have I found more than a very few bacilli in any of the indolent fibro-cellular lesions which are scattered throughout the organ. It is fairly certain that natural healing was occurring in this liver, though it was at one time much more extensively involved than were the livers of either of the other three animals. Nevertheless, in the lung, which shows microscopically characteristic fibro-caseous tuberculosis (Figs. 4 and 5), active foci with very large numbers of bacilli are present.

Conclusion.—Reviewing the experiment as a whole it may be said that it demonstrates above everything else that fibrosis and natural healing may occur in guinea-pigs infected with tubercle bacilli without any form of treatment at all. But this healing does not indicate more than a local reaction, for in other parts of the body the process is progressive. Inasmuch as the particular sample of antigen used is not regarded as entirely satisfactory, the experiment does not afford data for any expression of opinion as to the value of this form of treatment. If any potency is to be ascribed to the antigen, stress might be laid on the very distinct difference in the involvement of the lymphatic glands in the treated and the untreated animals. But if the treatment is held to be responsible for this, the benefit to the animals is obviously purely local, for the disease is progressing actively elsewhere, notably in the lung of No. 5. If, on the other hand, it is held to that the antigen is worthless, the guinea-pigs Nos. 4 and 5 afford examples of the natural local retrogression of tuberculosis in these animals.

Exp. 2 (6a) (Chart 2).—In this experiment an attempt was made to immunise guinea-pigs before infecting them. Twelve animals of varying weights received weekly injections of antigen for five weeks. At the end of this time four had died, but the eight survivors, together with six controls, were inoculated subcutaneously with a culture of human tubercle bacilli. After an interval of a month the treatment was



continued. By the middle of October four of the treated animals had died or been killed, and the remaining four were given two large doses of antigen, exhausting my supply of the particular sample, which by this time had been discredited. They were subjected to no further treatment. All the animals were allowed to die naturally or were killed when moribund. The weight chart is highly irregular and periodic falls, due to bad feeding, are obvious. It will be noticed how closely these variations correspond in the treated and the untreated animals. If anything, the treated animals appear to have been adversely affected by the antigen: the average duration of life was shorter in them than in the controls, one of which is still alive 158 days after infection, but, on the other hand, there was no immediate response to the two last massive doses of antigen, such as might have been expected.

Conclusion.—The experiment demonstrates how widely individual guinea-pigs may differ in their response to infection with tubercle bacilli. In

all the animals the disease was generalised, but the degree of involvement of the different organs varied considerably in different animals. There is, for example, abundant evidence that tubercle bacilli invariably reached the liver quite early in the infection, yet the hepatic lesions in different animals varied enormously in extent and intensity. And the same picture of retrogression in one place, with active progression elsewhere, is seen in this experiment as in the previous one. One untreated animal, No. 17, resembles in its lesions almost exactly the treated animals 4 and 5 of the first experiment. There is the same shrinking and scarring of the lymph nodes throughout the body, and the same fibrosis of the liver and spleen; but pulmonary foci show enormous numbers of bacilli. Quite often active tuberculosis with demonstrable bacilli can be seen in an organ, together with advanced fibrosis and old caseation with calcification. And a careful examination of the animals in this experiment demonstrates beyond doubt that much more stringent standards of cure must be demanded than have been accepted in the past before cure of tuberculosis in guinea-pigs can be claimed.

TABLE I.

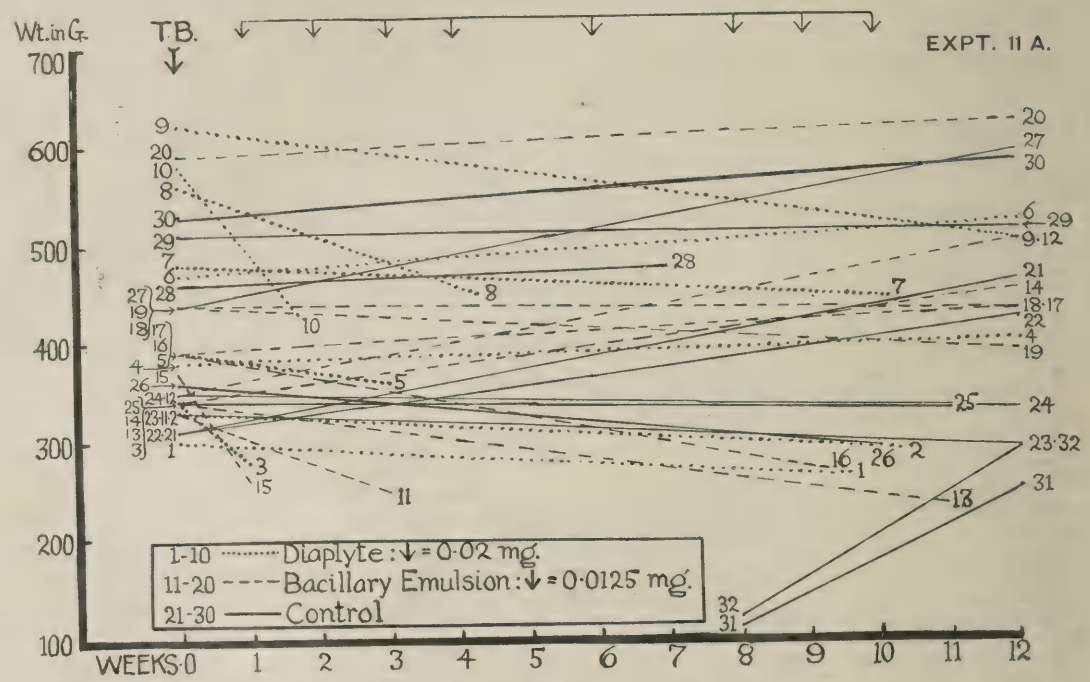
A = diaplyte. B = B. emulsion (tuberculin). C = controls.

—	Average weight in g.		Average loss or gain in g.	Average duration of life. Possible maximum 84 days.
	At beginning of exp.	At end of exp.		
A, 1–10	445	394	−51 (−11·2 %)	53·2
B, 11–20	398	382	−16 (− 4 %)	67·4
C, 21–30	394	424·5	+30·5 (+ 8 %)	78·4

TABLE II.—*Boars Alone.*

A, 1–10	418·7	374·4	−44·3 (−10·5 %)	47·1
B, 11–20	375	346	−29 (− 8 %)	63·0
C, 21–30	364	371	+ 7 (+ 1·9 %)	72·8

Conclusion.—As in the previous experiments, it has not been possible to distinguish absolute differences between treated and untreated animals. The local lesions and the palpable glands in the living animals are all in much the same condition, and no striking differences have been seen in the naked eye or microscopic lesions in those which have died.



Exp. 3 (11a) (Chart 3).—In this experiment 30 guinea-pigs were inoculated with human tubercle bacilli and divided into three equal groups; 1–10 were treated with diaplyte antigen (St. Mary's), 11–20 with bacillary emulsion (tuberculin), and 21–30 were used as controls. Inasmuch as the experiment has only lasted 12 weeks, too much cannot be claimed from it. Adopting the criteria of the duration of life and the body-weight, it will be seen that the best results are in the untreated guinea-pigs, and the worst in those treated with the diaplyte. The differences may be expressed in tabular form by averaging the weights and duration of life (Table I). At the end of 12 weeks 3 animals were alive in group 1, 6 in group 2, and 7 in group 3.

A possible fallacy in Table I. lies in the fact that some of the animals still living are sows, and therefore pregnancy cannot be absolutely excluded, though the animals have been segregated as far as possible. No. 7 when examined was found to contain three very early embryos, and No. 20 gave birth to two healthy animals, Nos. 31 and 32, in the eighth week of the experiment, since when she has been kept in a separate cage. But eliminating the sows, the figures show much the same results, though the figures for the control animals are most severely affected by this procedure. The figures for boars alone are given in Table II.

Evidence of healing can be found in many of the animals, though not to such an advanced degree as in the previous experiments in which the animals were examined at a much later date after infection.

General Survey of Results.

The conclusion which can be fairly drawn from the experiments is that the evidence which is usually brought forward in demonstration of the cure of tuberculosis in guinea-pigs is invalid. Such indications of healing as have been described occur naturally in untreated animals; further, they do not indicate any increased resistance to the tubercle bacillus in the animal itself, for they are local in their manifestations, and are associated with the progress of the disease elsewhere in the body. The original observations in support of Dreyer's treatment are, in the absence of adequate controls, quite inconclusive, and the question whether or not this antigen is of value in the treatment of tuberculous guinea-pigs can only be answered by further experimentation. In my experiments it has not been possible to demonstrate any curative action of the diaplyte antigen. There is, however, a good deal to suggest that the antigen had an adverse action on

the guinea-pigs treated with it, even in comparison with bacillary emulsion. It is possible that a different and favourable result might have been obtained by more careful dosage, although this is mere supposition.

We recognise every day in the post-mortem room healed tuberculous lesions in the caseous but completely encapsuled focus, the calcareous gland, and the scarred and puckered lung. It may be that such a lesion actually contains living and virulent tubercle bacilli, yet if it is securely encapsuled and shut off from the rest of the body it is regarded as a healed lesion. If, on the other hand, a progressive even though slow reaction of the surrounding tissues indicates that the lesion was still active it cannot be said that the patient was cured in respect to this particular infection, for we know from experience the readiness with which such latent foci may light up.

If such stringent criteria of cure are demanded for the human being, there is no reason why a lower standard should be accepted for the guinea-pig, especially when it is remembered that these animals are used in such experiments as have been discussed in this paper actually as indicators.

SERUM DIAGNOSIS IN SYRIA:

AN ANALYSIS OF 2868 CASES.

BY E. H. R. ALTOUNYAN, *M.C.*, M.D., B.CH. CAMB.

(*Abstract of M.D. Thesis.*)

THE following account is an abstract of work undertaken between 1921 and 1923 to estimate the value of serological tests in syphilis, tubercle, dysentery, typhoid, and typhus for the population in Syria. The clinical diagnosis has been confirmed by Dr. A. A. Altounyan, of Aleppo.

1. *Serum Diagnosis of Syphilis.*

(*a*) *Wassermann Reaction.*—This reaction was tested in 1783 cases, with Rochester Row technique, and heart cholesterin antigen prepared by Dr. E. L. Kennaway. The series under consideration covers a period of two years (1921–23); it includes the sera of 1783 individuals and is exclusive of controls and re-testings. The age of subjects ranges from 11 months to 75 years; all tests were performed by the author, using a uniform technique. The bulk of material was obtained from hospital out-patients; normal sera were obtained from the hospital staff, the free clinic, and in-patients awaiting major operations. In order to economise time and material and to minimise the risk of gross errors, which under the circumstances could not be checked by another laboratory, the reaction was carried out once a fortnight and the number of sera to be examined was maintained at a minimum of 50. In instituting the Wassermann reaction (W.R.) in Aleppo, it was considered desirable to estimate the percentage of positive results likely to be obtained from the routine examination of patients presenting themselves at the hospital. Owing to the great prevalence of malaria, it was thought necessary to endeavour to appraise its effect on the W.R. Of 1263 cases taken from persons not suffering from acute malaria or exhibiting gross signs of chronic malarial infection, 13·5 per cent. were found to give a positive W.R. In two cases in which the blood examination was repeated with contradictory results, no clinical evidence of syphilis was found. In the remainder, the diagnosis of syphilis was substantiated by physical stigmata or the results of anti-syphilitic treatment. This percentage of active syphilitics is comparable to the figures given by workers in France, England, and America. Of 135 cases suffering from obvious signs of chronic malarial infection, 11 per cent. were found to give a positive W.R. It may be assumed therefore that chronic malaria has no appreciable effect on the W.R. Of 21 cases of acute malaria, confirmed by the examination of the peripheral blood, 2 cases, or 9·5 per cent., gave a positive W.R. The anti-complementary phenomenon observed by other workers was well seen in 6 cases (30 per cent.). Of 152 cases taken from the venereal clinics, 48 per cent. gave a positive and 21 per cent. gave a suspicious reaction. These cases were examined as a test of the sensitiveness and accuracy of the general technique. Three cases of leprosy and 1 case of sleeping sickness (*Trypanosoma gambiense*) all gave negative reactions. Eight cases of pyrexia, due to infection with various organisms (non-malarial), all gave negative reactions.

TABLE I.—*Results Obtained in the Sera of 1783 Individuals Examined by the W.R. (Rochester Row Technique) at Aleppo.*

Groups.	No. of cases.	Positive.	Weak positive.	Doubtful.
		Per cent.	Per cent.	Per cent.
I. General	1263	13·5	9·1	—
II. Malarial (chronic)	135	11	12	—
III. Acute malaria ..	21	9·5 (2 cases)	30 (6 cases)	—
IV. Orphanage ..	212	26·8	14	—
V. Venereal clinics ..	152	48	10	11

N.B.—For practical purposes no reading less than "Positive" is considered as significant. In the case of known syphilitics, "Weak positive" and "Doubtful" readings are considered to be indications for the continuance of treatment.

Conclusions.—(1) Chronic malaria has no appreciable effect on the W.R.; (2) acute malaria has an undoubted effect in increasing the anti-complementary powers of the serum (if this is borne in mind, "false" positives will be of very rare occurrence); (3) pyrexia, due to non-malarial infection, has no effect on the W.R.

(*b*) *Sigma Reaction.*—This reaction was tested in 227 cases. Dreyer-Ward technique. Antigen prepared by Dr. H. K. Ward, of Standards Laboratory, Oxford. It was found impossible to carry out a large series of comparative tests by both methods, and in view of the work already published this does not seem to be of first importance. A sufficient number of comparative tests were done, and compared with the clinical findings, to satisfy the author that his interpretation of the technique was approximately correct. The sera of 227 individuals were tested. Of these 67 proved positive and 160 negative; 16 cases of discrepancy between the two methods occurred. In three instances the balance was in favour of the W.R., and in two instances in favour of the Sigma reaction (S.R.). One case of leprosy was returned as positive (2·6 units). A special study was begun on syphilitics under treatment, and the results in 10 cases (involving 52 tests) accord with those published by the Medical Research Council.

Conclusions.—(1) The S.R. appears to be of as great diagnostic value as the W.R.; (2) the technique of the S.R. is simpler, but the reading of results requires greater care and experience; (3) in the study of syphilitics undergoing treatment, the S.R. is undoubtedly the method of choice; (4) in the serum diagnosis of syphilis, workers will continue to use both methods in the elucidation of difficult cases; (5) the possible influence of malaria, leprosy, yaws, &c., requires careful investigation.

2. *The Complement-Fixation Test for Tubercle.*

Technique.—Besredka's antigen,[1] 501 cases. As for W.R. with following modifications: Serum not diluted, complement used 3, 4, 5, 6 M.H.D. Incubation time one hour at room temperature, one hour at 37° C. in incubator. Readings taken at once. The antigen was used undiluted, 1·5 unit volume to each tube. I subjected 501 cases to the complement-fixation test; the results agree in the main with those of

[1] For Besredka's antigen see Annales de l'Institut Pasteur, 1921, xxv., 291.

seven observations by other workers given in Table III. Table IV. compares my results with those of Rieux and Bass, also using Besredka's antigen and working with the same technique. It will be observed that in each case the highest percentage of positive readings is obtained in cases of pulmonary tuberculosis with positive sputa. In each case tuberculous peritonitis cases give low readings. The percentage of "false positives" is approximately the same. There is a striking difference in the percentage of positive results given by cases of pleural and glandular infection.

TABLE II.—*Analysis of the Complement-Fixation Test for Tubercle in the Sera of 501 individuals.*

T.B. suspect	80	64	98	91
Tuberculous (all cases) ..	156	75	274	83
Normal	148	11·5	203	14

N.B.—These results are strictly comparable except in the class labelled "T.B. glands." The author's cases were all lymphatic infections of the neck, axilla, or groin, while Rieux and Bass's figures are confined to bronchial gland infections.

As an outcome of the experience gained in these cases, I submit the following reflections:—

1. The time allowed for the fixation of complement must be ascertained accurately by experiment for each technique. It can be assumed that this will certainly be longer than that required in the W.R. At present I allow two hours. An extension of this time, as suggested by Aronson and Lewis, would possibly be advantageous. At the same time the percentage of "false positives" obtained (14 per cent.) is already considerably higher than the average. Allowance might be made in the readings in view of the compensating advantages of a more stable fixation.

2. Workers in France, England, and America agree that the highest percentage of positive results is obtained in cases where the diagnosis of tuberculosis is based on the finding of tubercle bacilli in the sputum. Such a conclusion is highly satisfactory. It is, however, to be regretted that the classification of cases according to the site of the tuberculous lesion is not more frequently made.

3. The cross-fixation phenomenon with syphilitic sera is a serious factor in all tests where the Besredka antigen or whole tubercle bacillus emulsion is used. In 29 of my syphilitic cases there were 20 cross-fixations with the tuberculous antigen.

4. The effect of hyperpyrexia on the reaction requires further elucidation. Four cases of the author's (all positive), occurring in the course of typhus, typhoid, small-pox, and sleeping sickness, suggest that this may prove a source of error.

General Conclusions.—(1) It is impossible to say, by a consideration of the general physique, or a detailed examination of the particular focus of disease, whether, in any given case, we are likely to find a plentiful or scanty production of antibodies in the blood; (2) it may be hazarded that, on the whole, we are likely to obtain a strong reaction in an incipient case and a weak or negative reaction in a terminal case of tuberculous infection, but the exceptions to this dogma are many, and reliance on it may occasionally prove dangerously misleading; (3) the phenomenon of the non-specific cross-fixation of complement appears to be due to the employment of whole tubercle bacilli in the preparation of the antigen. On extracting the bacilli with alcohol and ether, the sensitiveness of the antigen may, to some extent, be impaired.

3. *Serum Diagnosis of Chronic Bacillary Dysentery.*

In this series 181 cases were tested, Dreyer's standard cultures of Shiga and Flexner V, W, X, Y, Z being used (incubation four and a half hours in water bath). The classification of normal and dysenteric individuals adopted in the accompanying tables is necessarily arbitrary. Few persons living in the near East escape, at one time or another, an attack of acute intestinal catarrh. The amœbic and bacillary types seem to be about equally prevalent. A "normal" individual is taken as one who at the time of examination (and within recent memory) is not suffering from some chronic intestinal disorder. The "dysenteric" patient is not so classified until he has undergone a thorough examination, including an investigation of stools for amœbæ and parasites, and a search in the blood for malarial plasmodia. In short, persons suffering from chronic intestinal instability in whom malaria, amœbic dysentery, and the presence of large numbers of intestinal parasites have been excluded, are classed for the purposes of this investigation as chronic dysenterics. The longest period of debility in this series is 20 years. The experience gained in one case of two years' standing, cured by the administration of santonin and the expulsion of large numbers of round worms, has led to the routine administration of a vermifuge before proceeding to the more elaborate investigation of any patient.

The comparisons between the normal and dysenteric groups is given in Table V. Taking 10 agglutinin units as the minimum standard of positivity, it will be found that normals show 38 per cent. and dysenterics 74 per cent. of positives. If the sexes are differentiated, it will be seen that females give a considerably higher percentage of positives (both in the dysenteric and normal group) than males.

In the dysenteric group, the relative importance of the types of bacillary infection is shown in Table VI.

It will be observed that Flexner Y is by far the commonest, and then W, while V, X, Z and Shiga occur with about equal frequency. On contrasting the normal and dysenteric groups in respect of the six types of dysentery bacilli, we observe (1) that over 10 agglutinin units obtained with Flexner W or Y may be regarded as suggestive; (2) that Flexner Z is very rarely met with in the normal group; (3) that reactions to Flexner X occur in about the same proportion with normal and dysenteric sera.

TABLE V.—*Number of Cases Giving 10 Units and over with any one of Six Types of Dysentery Bacillus (Shiga and Flexner Group).*

—	No. of cases examined.	No. of cases giving 10 units and over.	Percentage of cases giving 10 units and over.
Normal cases (both sexes)	112	43	38
Dysenteric cases (both sexes)	67	50	74
Normal male cases	63	21	33
Dysenteric male cases	27	15	55
Normal female cases	49	22	44
Dysenteric female cases	40	35	87

TABLE VI.—*Percentage of Cases giving 10 Agglutinin Units (and over) when tested against* B. dysenteriæ, *Shiga and Flexner V, W, X, Y, Z respectively.*

Analysis of 181 Cases.

Male and female.	Normal.		Dysenteric.	
	No. of cases.	Percentage.	No. of cases.	Percentage.
B. dys. Shiga	5	4·5	10	13
B. dys. Flexner—				
V	5	4	9	13
W	13	11·5	23	35
X	16	14	10	16·6
Y	23	20	33	57
Z	2	1·7	11	16

Conclusions.—(1) The standard agglutination tests with the Shiga-Flexner group of dysentery cultures, though primarily designed as a supplementary aid in acute and subacute infections, may have a large field of usefulness in helping to determine the prevailing type of infection in the dysenterics of any given population; (2) that such an investigation may prove to be of more than academic interest is suggested by my experience in a few cases treated by dysenteric vaccines made up of organisms corresponding to the prevailing types (Thomson's detoxicated vaccines); (3) it is possible that the standard agglutination tests may be of value even in the diagnosis of chronic dysentery; though the series of single tests reported by the author is not, and cannot be, conclusive, yet it is reasonable to suppose that repeated tests on the same individual, in a large number of cases, may enable one to formulate some working hypothesis as to the relative significance of slight irregular variations in agglutinin values, obtained with a particular organism, in any given individual.

4. *Serum Diagnosis of Typhoid.*

In this series of 107 cases, Dreyer's standard cultures of *B. typhosus*, *B. paratyphosus* A and B, *B. enteritidis* Gaertner, and *B. aertrycke* were used. Incubation two hours.

1. Of 56 normal controls significant agglutinin values were recorded in 3 per cent. of cases. Of 51 cases of clinical "typhoid fever" 78 per cent. gave high agglutinin values with *B. typhosus* cultures, and there were four cases regarded as due to paratyphoid infections.

2. A consideration of Table VII. suggests that the population as a whole shows signs of having recently passed through a paratyphoid epidemic (probably paratyphoid B). There is a certain amount of evidence to prove that in the presence of an active *B. typhosus* infection paratyphoid agglutinins of a value which would not ordinarily be regarded as significant are raised and in some cases attain a value far exceeding that produced by the active infection.

3. A further consideration of these tables leads one to think that what is true of paratyphosus B is also true of the *B. enteritidis* Gaertner. It becomes apparent that there is a considerable Gaertner infection of the general population and that infection with *B. typhosus* raises considerably the value of its agglutinin residues.

TABLE VII.—*Agglutinin Values obtained with* B. typhosus, B. paratyphosus *A and B*, B. enteritidis *Gaertner, and* B. aertrycke *in 56 Normal Individuals and 57 Cases Diagnosed as Typhoid.*

Group.	Cultures.	No agglutination.		2–5 units.		5–10 units.		10–20 units.		20 units and over.	
		C	%	C	%	C	%	C	%	C	%
N	*B. typh.*	49	87	5	8·9	0	—	2	—	0	—
T	*B. typh.*	4	7·8	3	—	4	7·0	13	27	27	57
N	*B. Para.*	55	98	0	—	1	—	0	—	0	—
T	*typh.* A.	45	88	0	—	0	—	3	—	3	—
N	*B. para.*	50	89	3	—	3	—	0	—	0	—
T	*typh.* B.	41	80	1	—	0	—	1	—	8	17
N	*B. enter.*	49	87	0	—	5	8·9	2	—	0	—
T	Gaert.	40	78	0	—	3	—	4	7·8	4	7·8
N	*B. aer-*	53	94	0	—	0	—	3	—	0	—
T	*trycke.*	45	88	0	—	2	—	3	—	1	—

C = Cases. N = Normal. T = "Typhoid."
B. typh. = *B. typhosus.* *B. enter.* Gaert. = *B. enteritidis* Gaertner.

Note.—Of the five normal cases showing 2–5 units with *B. typhosus*, one is known to have had enteric ten years previously. Of the two normal cases showing 10–20 units with *B. typhosus*, one had a severe attack of typhoid five years previously, and the other six years before. Both were members of the hospital staff and were examined in the general course of routine. Neither give any signs or symptoms of ill-health. Stool cultures were not made. The remaining four cases giving 2–5 units with *B. typhosus* have not been accounted for.

4. The significant agglutinin value may be regarded as being one of a minimum of 10 units, though undoubted "typhoid" infections may occasionally register, even at an advanced stage of the disease, considerably lower readings.

5. Though positive hæmocultures were only obtained in five cases, in two of these it was the only means of distinguishing by a single test between typhoid and paratyphoid infections.

6. The coagglutination of *B. paratyphosus* B with *B. aertrycke* is very noticeable.

Summary.—(1) Even in populations where typhoid is endemic (as in Syria) single agglutination tests are of considerable value in diagnosis after the eighth day; (2) the phenomenon of coagglutination requires further study; (3) it is desirable in any investigation of the enteric group that agglutination tests should be made with as many organisms as possible.

5. *Serum Diagnosis of Typhus, Weil-Felix Reaction (B. Proteus X 19).*

Sixty-nine cases were taken from a small epidemic originating among Greek refugees in the autumn of 1922. The general population (immunised by the epidemic of 1916) escaped lightly. Dr. N. Ishkhanian interested himself especially in the working out of the technique, and many of the sera were collected by him at personal risk and inconvenience.

Technique.—1. The blood was collected in agar-lined tubes (A. D. Gardner's technique), according to the author's modification of Thompson's method. 2. The culture used was procured from the Lister Institute collection of type cultures. It was labelled Lister 67. In the laboratory it was maintained by sub-culture once a month at room temperature, after a preliminary 24 hours' incubation at 37° C. For the emulsion a fresh 18 hours' growth on agar was employed. 3. Bacillary emulsion: At first fresh emulsions of the live organisms were used, of an opacity corresponding to that of the standard cultures. Latterly it was found that emulsions of bacilli killed by exposure for one hour to 60° C. remained sterile, and preserved their sensitiveness for two months at least. All attempts to secure formalinised emulsions corresponding to the standard cultures failed. It was repeatedly found that

within a week such an emulsion would fail to agglutinate with even strong positive sera. 4. Dreyer's macroscopic technique was adopted throughout. 5. The time and range of temperature allowed for agglutination are important factors in the test. It was eventually decided that the best results were obtained by three hours' incubation at 37° C., followed by two hours at 54° C., the readings being taken next morning. 6. Controls: As it was impossible to obtain permanent emulsions of stable sensitiveness, special attention was given to checking the sensitiveness of each culture for each test by the use of the following controls: (*a*) A normal serum was tested in a 1 : 25 dilution. If agglutination occurred, then that particular batch of emulsion was rejected; and (*b*) the pooled serum of 10–15 typhus patients, known to give a strong agglutination titre, was preserved (in capsules and a series of small bottles) mixed with an equal volume of pure glycerine. Of this stock a 1 : 250 dilution (=1 : 125 of pure serum) was put up with each batch of sera to be tested. An emulsion was considered satisfactory if complete sedimentation took place in the tube containing the stock serum.

Results.—1. Of 57 typhus patients examined by the Weil-Felix reaction, 3 proved negative. Of these, 1 was lost trace of, 1 was examined after the crisis, and 1 proved positive on re-examination on the tenth day. The earliest authenticated day on which the reaction was obtained is the fifth, the latest four weeks from the onset. The highest effective dilution was 1 : 5000, the lowest 1 : 50. A large proportion reacted in dilution of 1 : 250 and more. 2. Of the 9 cases recorded as controls, there was one case of a doubtful reading (dilution 1 : 50) in a normal individual. In 3 cases of typhoid a negative reading was given. (It must be stated that many more normal controls than those given here were actually carried out, as it was the practice to include in each batch of tests at least one normal individual.) 3. I was unable to confirm the observations of K. Bauer on the effect of typhus serum on the W.R. 4. The effect of typhus serum on typhoid organisms was investigated in 3 cases with negative results.

Note.—The strength of the reaction does not correspond to the gravity of the disease. Mild cases may give strong reactions, but a high reading was also obtained in a patient shortly before death. There is no authenticated case in the literature of diagnosis having been made serologically before the fourth day. It should be possible for workers in countries where typhoid is endemic to ascertain the precise influence of typhoid agglutinins on *B. proteus*.

My thanks are due to Drs. Thoulons, Maire, Borel, and Chopin, of the French Medical Service; to Drs. Sabri Farah and Lutfi, of the Aleppo Venereal Clinics; and to Drs. N. Ishkhanian and P. Hovnanian for the supply of interesting clinical material. Dreyer's technique was carried out by Miss Bayramian and Miss Setyan working in the hospital laboratory. Much valuable advice was given by Dr. A. D. Gardner, of Oxford University.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

COMBINED SECTIONS OF MEDICINE, PATHOLOGY, AND THERAPEUTICS.

THE USES AND LIMITS OF VACCINE-THERAPY.

THIS subject was discussed at a combined meeting of the Sections of Medicine, Pathology, and Therapeutics. Dr. A. J. CLARK, President of the last-named section, occupied the chair.

Sir ALMROTH WRIGHT, in introducing the discussion, said it was always necessary to decide what was the value of an inoculation, and in dealing with a particular patient, the question arose whether a vaccine would do him any good—i.e., whether a stated dose of the vaccine would have any good effect. It really became a matter of making a complete immunological diagnosis as to the dimensions of the infection rather than of the particular site involved. In a septicæmic case one required to know whether the patient had the power of making an active response to a vaccine. In most cases one had not very exact details as to the amount of response to infection, hence it was necessary to employ indirect inference. The experienced mind with a broad vision recognised that typhoid and anthrax were diseases of the same kind—namely, diseases in which the infecting microbe got into the blood, therefore what would work in one case would probably work in the other also. As living microbes, when injected, acted only after they had been dissolved, it was clear that dead microbes could be used with the same effect as living microbes. The mind which refused to accept laboratory results, or which believed nothing that was not evident to the naked eye, was not of any help in devising new methods. Yet laboratory work showed that when dead microbes were injected into a patient the power of his blood could be increased a thousandfold. Indirect inference was better than direct, because details of cases varied so enormously, not only in regard to the strength of the infection, but also the local condition of the patient and his power of resistance. One could not say that because a hundred cases of phthisis apparently similar acted in a certain way, therefore the hundred and first would so act. In regard to the dose of vaccine, it was necessary to have a general outlook. It was known that a healthy man could stand a very large dose of any vaccine and could respond to it; therefore, if one had a man who had no microbes, he could be expected to respond to a big dose; but if he already had some microbial invasion he had, when an injection was made, to deal with two quantities—those he already had in his body and those injected, and he became sick. For that reason the dose for an infected man had to be smaller than that for a healthy man. The importance of diagnosing the volume of the patient's infection thus became paramount. There was a great need to standardise antistaphylococcic serum; many attempts were being made to do this, but he believed none had yet succeeded. Recently, immuno-transfusion had been carried out—i.e., blood was withdrawn from a donor and introduced into the patient with the idea of supplying the latter with the protective substances he was no longer able to manufacture for himself. This was a valuable method, though it, of course, had its limitations. One valuable fact had emerged—namely, that inoculation of a substance which had a specificity to a particular disease, also produced substances protective for other diseases. That might be regarded as a provision of Nature, for it would be a large order to provide specific substances for each separate disease. He believed it should be possible, in the case of a patient seriously ill with pneumonia, to hasten, by inoculation, the crisis and the recovery, instead of waiting for Nature to bring it about in a more leisurely fashion. To do that it would be

necessary to ascertain what was the patient's critical dose. With regard to tubercle, it had been found, in the last six months, that it was a very easy matter indeed to grow tubercle bacilli in the blood, and in enormous numbers. He thought the future treatment of tubercle would be along cataphylactic lines.

How should one judge of results? Most people would answer, by statistics. But statistics, to be complete, needed to be so many-sided that it was difficult or impossible to carry away any general impression from them. Really, one tested most by experience of cases, history, examination, control, after-care. If a desperate case got well, one was justified in attributing the result to one's treatment.

Preventive Inoculation.

Sir WILLIAM LEISHMAN said he had but little first-hand recent knowledge of vaccine-therapy to offer. He had had a fairly large experience in preventive inoculation, and what one learned in that regard was very useful in the use of vaccines for the purposes of treatment. Not only had preventive inoculation been used against typhoid, but also against influenza, especially in the last big epidemic of it. Probably, however, it was not the bacillus of Pfeiffer which was responsible for this disease, but some ultra-visible virus. A vaccine containing streptococci and pneumococci played a great part in prevention. He reserved his opinion as to the value of sensitised vaccines, lipo-vaccines, sero-vaccines, detoxicated vaccines, &c. The effort was to extract from the germ concerned the immunising agent with as little damage as possible, to free it from its toxic ingredients which caused severe reactions and were of no use in immunising, and to get the essential substance in a condition in which it could be easily manipulated and the dosage standardised. He saw no reason for departing from the method of subcutaneous inoculation; the oral method had not yet been clearly settled. Bacteriologists could not feel very happy about vaccine-therapy largely because of the methods by which material was prepared for investigation and the production of vaccines. Often the material was sent by post to a bacteriologist or to a research institute; there was a short statement as to what the patient was suffering from, and a request was made for a vaccine to be at once prepared. The conditions under which the material was prepared were not known and it might have been a long time in transit, perhaps it suffered extremes of temperature, which killed off the sensitive microbes, and the worker found a vigorous microbe surviving, which he cultured, but which was not, probably, the causal factor of the patient's condition.

Dr. W. GORDON pointed out that, especially in acute cases, the dose of vaccine very frequently given was excessive, and hence was dangerous. He related five cases in which that was strikingly borne out. In his first case death nearly followed the use of an ordinary dose. It was that of a man with streptococcal septicæmia, the organism being grown from his blood. He was given a quarter of a million, and no bad results ensued. Forty-eight hours later half a million were given, and within four hours of the second dose his syncope was so bad that he nearly died. In a second case—streptococcal infection of lung—the same initial dose was given and there was no bad symptom. In view of the other case, a 72-hour interval was observed, and another quarter of a million given, and within four hours he had a similar attack of syncope to the other case. To the remaining cases he gave only 40,000, and the results were quite satisfactory.

Dr. A. P. BEDDARD said that in England the chief prophylactic use of vaccines was in catarrhal conditions of the respiratory tract. His experience was that the more nearly a case was to being a chronic carrier of the infection, the more difficult was it to get any good result from the use of vaccine. He had found a mixed autogenous vaccine superior to a stock vaccine, and it was important to ascertain the bacteriology of the pharynx as well as of the sputum. In a case of a series of outbreaks of streptococcal lobar pneumonia he had been able to abort the attacks by subcutaneously injecting at once a 100,000 dose of autogenous vaccine, followed in 12 hours by a double dose. A difficult class of case was that where infection was in one of the tubes of the body, and, to a less extent, that applied to the respiratory tract; and the difficulty of getting a successful result in those cases was enhanced if obstruction also was present. Many of the failures ascribable to vaccine-therapy he regarded as more or less avoidable. The full bacteriology of the case might not have been ascertained. Or the dosage might be at fault. Too often dosage was determined by rule of thumb based upon apparently similar cases. It was especially difficult in acute cases to get the right dose. Another cause of failure was neglect of local treatment and the presence of mechanical defects. Yet after all these causes had been eliminated there were a number of cases in which the treatment by vaccines as ordinarily carried out was inappropriate in one class and uncertain in the other; and if Sir Almroth Wright's newer method of tackling these cases fulfilled its promise, it would mark yet another advance among those associated with his name.

Vaccination in Chronic Colds.

Dr. GORDON MCKASKIE gave his experience of vaccination for people who suffered from chronic colds. He advocated that the specimen should be incubated as soon as it was obtained; otherwise the more delicate organisms might die out. For that reason it was best to collect the specimen in a bacteriological laboratory. In most of his preventive inoculations he had secured complete immunity, and when patients feeling the symptoms of a cold coming on were injected, the cold was aborted in 24 hours. He had used vaccines extensively also in chronic diseases. In infective arthritis, after removing the obvious source of infection, he had had good results. But in chronic bronchitis his results had not been satisfactory, though in one or two cases in which streptococci were present there was improvement. He had noted no effect in cases of surgical tuberculosis. The opsonic index was now known not to be the valuable criterion in treatment that had been expected.

Sensitised and Raw Vaccines Compared.

Dr. R. ARMSTRONG said that during the last few months he had been making a careful comparison of the properties of the sensitised with those of the raw vaccines, using the pneumococcus for the investigation. He used equal doses of each in rabbits, and estimated the antibody content of the sera. As a result of administration intravenously of sensitised vaccine there was a speedy and complete elaboration of the antibody charge of the vaccine. The stage of diminished immunity persisted for a day, and then slowly immunity developed; at the end of the third day it had only attained 0·6 of the lethal dose for a mouse, but by the sixth day there was a dramatically large increase in the immunity. In the case of the administration of raw vaccine, however, the immunity persisted unchanged for many days. In the case of sensitised vaccines it was far different when giving a course; active immunity was deferred until the seventh day, and its degree was tremendously reduced. He thought this cancellation effect could be explained by successive neutralisations of the doses of sensitised vaccines. This research seemed to show that the profession was, as yet, merely on the threshold of treatment by vaccines. He agreed that the old-fashioned subcutaneous injection of heat-killed vaccines was the most valuable reagent possessed for producing active or passive immunity at present, and more work was needed before embarking on the extensive application of sensitised vaccines, especially in acute infections.

ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.

NEPHRITIS.

A MEETING of this Society was held on Dec. 7th and 14th, when a discussion took place on nephritis, with special reference to the physiology and pathology of the kidney. The discussion was opened by Prof. E. P. CATHCART, who gave a brief survey of the modern views with regard to the physiology of the kidney and its function. He referred particularly to the "filtration re-absorption" theory of urinary excretion and also to the part played by the kidney in the regulation of the hydrogen-ion concentration of the body fluids.

Prof. J. SHAW DUNN (Manchester) prefaced his remarks on the morbid changes in the kidney in nephritis by referring to two important conceptions in the study of these changes. The first was the conception of the glomerulus and tubule as a unit of renal structure from the anatomical point of view. Any damage to a glomerulus which produced changes quantitative or qualitative in its filtrate must also affect the function of the tubule; while any disturbance of the vessels of the glomerular tuft must affect the blood-supply of the tubule. The second conception was that of reserve function. The destruction of a large part, or the whole, of one kidney by a gross lesion such as tumour or tuberculosis was rarely followed by any evidence of renal inefficiency; and this was true also in some of the more diffused lesions of nephritis. Thus the clinical picture might give an imperfect indication of the extent of severity of the kidney lesion. The morbid histology of the various forms of nephritis was then described in detail.

Prof. T. K. MONRO gave a brief historical survey of the various conditions included under the term nephritis and referred to the classification into three types, one acute and two chronic. He inclined to the opinion that the secondarily contracted kidney—the chronic form of nephritis following on an acute attack—was perhaps the commonest form met with now in hospital practice. The features, clinical and anatomical, were intermediate between those of the large white kidney and those of the small red kidney. He went on to describe in detail the clinical and pathological features of these various types, referring particularly to the relation of the acute and chronic stages; and drew attention to the acute case which represented an exacerbation of an underlying chronic disease and also to the fact that apparent recovery from an acute attack might result in the return of the patient later with evidence of chronic disease. He then discussed the relation of the arterio-sclerotic kidney—admittedly of vascular origin—to the small red granular contracted kidney and pointed out that, though the latter might yet be found to be of arterial origin, the two conditions were clinically quite distinct.

Dr. ETHEL CRAWFORD described in detail the results of renal efficiency tests which had been carried out in a series of cases in the Royal Hospital for Sick Children, Glasgow. The children were under 13 years of age and were all suffering from inflammatory lesions. Three tests were selected for comparison: (1) The phenolsulphonephthalein test, (2) the urea-concentration test, and (3) the urea content of the blood.

Pigment Test.—In acute cases the excretion averaged 48 per cent.—generally low at onset but increasing as the symptoms subsided. In chronic cases—three months or longer—the average was 57 per cent. In a control series of 26 normal cases the excretion averaged 67 per cent. The test was found to be of no prognostic value.

Urea-Concentration Test.—In acute cases the average was 2·1 per cent., in chronic cases 2·8 per cent. The results of this test were found to be very misleading unless taken in conjunction with the urea content of the blood.

Urea Content of the Blood.—In acute cases the average was 76·6 mg. per 100 c.cm. In chronic cases 37. In normal controls the average was 39. It was high at the onset of the disease and remained high in acute cases, but diminished as a rule as the condition improved. This test was no guide to prognosis nor was it commensurate with the severity of the symptoms.

In general, Dr. Crawford said, these tests do not give any more definite evidence of the severity of the disease, or of the probable outcome. They do not give any help in distinguishing between acute, subacute, and chronic cases, and during the disease they merely corroborate the clinical symptoms.

In the discussion which followed, Prof. R. MUIR expressed the opinion that the time was not far off when we should be able to establish a definite relationship between the functional disturbances and the structural changes in the kidney in the various types of nephritis. He referred to the progress already made in the differentiation of the azotæmic and hydræmic types, and was especially interested in Prof. Dunn's remarks regarding the association of the hydræmic type with subacute nephritis. He found it difficult to harmonise the modern physiology—e.g., the filtration re-absorption theory—with the pathological facts met with in the disease.

The following also took part in the discussion: Dr. J. NORMAN CRUICKSHANK, Dr. J. R. C. GREENLEES, Dr. G. M. WISHART, Mr. INGLIS POLLOCK, Mr. W. W. GALBRAITH, Dr. J. FERGUSON SMITH, Dr. H. E. JONES, and Dr. W. SYME.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.—A meeting will be held at the Miller General Hospital, Greenwich, to-day, Friday, Jan. 11th, at 8.45 P.M. Mr. Willmott Evans, Dr. M. Davidson, Mr. C. A. Joll, Dr. Harold Pritchard, Mr. P. B. Roth, and others will show clinical cases.

SOCIETY OF MEDICAL OFFICERS OF HEALTH *Maternity and Child Welfare Group.*—A meeting of this Group will be held at the house of the Society, 1, Upper Montague-street, Russell-square, London, at 8 P.M., on Jan. 17th. Dr. William Cramer will read a paper on Vitamins and the Borderland between Health and Disease, illustrated by slides. The lecture is open to all those interested in Maternity and Child Welfare work, and members of the Dental and School Medical Groups are invited to attend.

MEDICAL SOCIETY OF LONDON.—The syllabus of the second half of the session 1923–24 has now been issued. The Lettsomian Lectures on the Treatment of Pulmonary Tuberculosis will be delivered at 9 P.M. on Feb. 18th, March 5th and 17th, by Dr. R. A. Young, and the annual oration will be delivered at 9 P.M., on May 5th, by Mr. Wilfred Trotter, on Certain Minor Injuries of the Brain. On Jan. 14th, at 8 P.M., a pathological meeting will be held. Dr. H. G. Butterfield will give a demonstration of his method and apparatus for micro-photography. On the 28th, at 8.30 P.M., Dr. G. Arbour Stephens will give a short historical note on Transfusion of Blood and Injection of Medicated Liquors as carried out in 1650–1700, and Dr. John Poynton, Mr. Twistington Higgins, and Dr. J. M. Brydone will communicate a paper on the Present Position of the Treatment of Pyloric Stenosis in Infancy. On Feb. 11th, at 8.30 P.M., a discussion on the General Symptoms and Remote Manifestations of Common Affections of the Nasopharynx, Accessory Sinuses, and Throat, will be introduced by Mr. Herbert Tilley, followed by Lord Dawson, Dr. John Poynton, Mr. W. M. Mollison, Dr. E. M. Callender, Sir Thomas Horder, Mr. C. W. M. Hope, Mr. E. D. D. Davis, and others. On Feb. 25th, at 8.30 P.M., a discussion on the Treatment of Fibroids of the Uterus will be introduced by Dr. Cuthbert Lockyer, followed by Sir George Blacker, Mr. T. G. Stevens, Dr. H. Williamson, Mr. Beckwith Whitehouse, Dr. N. S. Finzi, Mr. J. P. Hedley, Dr. Douglas Webster, and others. On March 10th, at 8.30 P.M., a discussion on the Disturbances of the Nervous System in Hyperpiesia will be introduced by Dr. Batty Shaw, followed by Sir Humphry Rolleston, Prof. Ernest Starling, Prof. W. Russell, Dr. James Collier, Dr. F. M. R. Walshe, Dr. Geoffrey Evans, and others.

Reviews and Notices of Books.

MASTER JOHANN DIETZ.

Translated by BERNARD MIALL. First published by Dr. Ernst Consentius. London: George Allen and Unwin, Ltd. 1923. Pp. 315. 12*s.* 6*d.*

Johann Dietz was a barber surgeon in the seventeenth century, who left behind him an autobiography in which he recorded his life from beginning to end, and this document, or its contemporary copy, is preserved in manuscript in the Royal Library of Berlin. The first version of the biography appeared some nine years ago under the editorship of Dr. Ernst Consentius, to whom permission was given not only for the printing of the manuscript, but for reproduction of any of the engravings necessary to supply the record with authentic pictures; this volume is a translation by Mr. Bernard Miall. It is a most interesting as well as profusely illustrated record of an adventurous career. From internal evidence presumably, Dr. Consentius states that the autobiography was not commenced until Master Dietz had reached his seventieth year, and the probability, therefore, is that the dating is not very strict, one episode reminding the writer of another, and that in turn requiring a sequel. Perhaps there is no maintenance of strict chronology, that may well be, but none the less we gather a remarkable picture of stirring times from one who lived, rejoiced, and suffered in them.

A member of the Guild of Barbers, Master Johann Dietz learned surgery in one of the normal methods of the times by serving on military campaigns—he went as doctor in the army of "the Great Elector" Friedrich Wilhelm, of Brandenburg. This distinguished prince, in support of the Hapsburgs and the Holy Roman Empire, or to annoy the King of France, took part in 1663 in a campaign against the Turks, and we have a fine description of the siege of Ofen, of military and medico-military proceedings throughout fierce warring, and of a weary journey back to Berlin. And in spite of the sensational nature of the episodes the story rings true, while it says much for the hero's thirst for adventure that almost immediately after arriving home we find him, in the most light-hearted way, accepting an offer made to him in a guest-house at Hamburg to voyage to the Arctic Ocean. Johann Dietz accepted an offer of 12 thalers monthly, to accompany three recent acquaintances for an unlimited time, and drew one month's pay in advance in order to buy a new medicine chest. And so he went a-whaling, in the course of which calling he describes Spitzbergen and Greenland, makes some amusing biological reflections, and details some dangerous voyaging back along the Norwegian coast with its fogs and hidden rocks.

The last part of the book is largely made up of the astonishing inconveniences and even unhappinesses of his career as a husband. He makes no secret of his view that he was caught, as to one of his alliances, by craft, a widow with three children securing him "after many fine opportunities and alternatives." He allows that he did his best to get out of the contract, which, however, was carried through although the bride's settlement seems actually never to have been paid.

But perhaps it was fair that Master Johann Dietz should pay in the unhappiness of married life for certain amatory episodes which he details with frankness in an amusing and informing narrative, every page of which reads like an imaginary journal by Defoe or Thomas Nash. The probable popularity of his adventures for public reading was, as a matter of fact, detected by one Christian Reuter, for it appears from one of the appendices to Mr. Miall's translation that the biography served as the text for that author's well-known German romance. This made its appearance in 1696, the author being almost contemporary with Johann Dietz.

HANDBOOK OF THE NEUROLOGY OF THE EAR.

Produced by Prof. Dr. G. ALEXANDER and Prof. Dr. O. MARBURG. Edited by Dr. H. BRUNNER, of Vienna, with the collaboration of eminent specialists. Vol. I., Part 1. Berlin and Vienna: Urban and Schwarzenberg. 1923. Pp. 699. Fr.48.75.

In recent years our knowledge of the reflexes and other nervous reactions originating in the ear, and especially in the labyrinth, has been rapidly increased by careful clinical investigations and by a long series of experiments on animals. The neurologist and the otologist have also been brought closely together in the study of the endocranial complications of ear disease and in the examination of the aural symptoms of certain cerebral tumours. The results of these observations are scattered through otological and neurological publications, and it is appropriate that a work should be published which deals with this borderland between neurology and otology as a whole. How extensive this borderland is may be judged from the fact that this large book is but the first half of the first volume designed to cover the subject. The first volume is to deal with the theoretical, the second volume with the clinical aspects of the subject. This volume is well printed and profusely and beautifully illustrated; it is without index or table of contents, and consists of a series of independent articles, each with its own contents-table and bibliography. They are very thorough and complete, and are written by well-known authorities in their respective subjects. Prof. Alexander describes the macroscopical anatomy of the nervous structures of the ear, Prof. Kolmer the microscopical, while Prof. Marburg deals with the development and anatomy of the nerves and central nerve-paths. Physiology is dealt with in a series of articles, including one on the outer and middle ear and one on the inner ear, and articles on localisation of sound, on perception of tone, and a full account by Prof. Magnus and Dr. de Kleijn of their experimental work on the otolith reflexes. Dr. Rudolf Leidler contributes a good discussion on vertigo, and Dr. J. Dusser de Barenne an interesting description of the physiology and neuropathology of the cerebellum.

All the contributions are of a high standard and when completed, the work will be of great value to neurologists and otologists alike.

SCIENTIFIC METHOD: AN INQUIRY INTO THE CHARACTER AND VALIDITY OF NATURAL LAWS.

By A. D. RITCHIE. London: Kegan Paul. 1923. Pp. 202. 10*s.* 6*d.*

Mr. Ritchie exhibits in this book an elaborate geniality, the affability of the schoolmaster who is a boy among boys, and is not too proud to use slang; but he has written a work that contains much information worth the ordinary reader's while to possess. He points out that inasmuch as no single mind can contain the whole of the results of modern scientific investigation, any man's opinion on most topics is bound to be superficial and based on hearsay. He therefore disclaims any attempt to survey the present state of scientific theories or to test their validity, but essays to state what kind of reasons there can be for holding any scientific theories, whether those of Pythagoras, Newton, or Einstein.

An introductory chapter dealing with the origins of science, its relation to metaphysics and to logic, a definition and a classification, leads to a discussion in Chapter II. of the ultimate data of knowledge and the classification of the data of experience. Chapter III. deals with natural laws, and Chapter IV. with the validity of laws, Chapter V. with measurement, and Chapter VI. with theories, while the concluding chapter is devoted to the limitations of scientific method and a consideration of science in relation to metaphysics. Mr. Ritchie's personal knowledge of experimental research gives point and interest to his illustrations. He is not, however, always scrupulously fair in setting out opinions with which

he disagrees. This appears in his discussion (on p. 132) of the justification of an average. The argument that an average of certain measurements is more likely to characterise the "true" value of the quantity sought to be measured is not, we think, disposed of by the remark: "The observer who imagines there is some real or true value, which can be attained by correctly calculating an average from a collection of different numerical results, is guilty of the absurdity of thinking that arithmetical calculations can supply better information about the external world than actual observation." He is guilty of no such absurdity; all he is guilty of is (*a*) a belief that several equally imperfect measurements are more likely to give a correct appreciation of the "truth" than one such measurement; (*b*) a theory that the value that gives a maximum probability to the concurrence of the measurements is the best approximation to the "truth" he can make. Neither proposition is absurd, the absurdity is really Mr. Ritchie's—viz., the tacit implication that "the observer" thinks that the quality of the observations to be averaged is indifferent. We do not believe that the most rabid exponent of the calculus of errors ever maintained any such proposition.

In discussing the genesis of discoveries, Mr. Ritchie is on firm ground. "The vital, if not the only, difference between the successful and unsuccessful investigator lies in the capacity to frame the appropriate generalisations that are presupposed in any research. Probably it is more a matter of instinct than of argument. The generalisation that is needed may be one that only has a very minute degree of probability a priori so far as any logical analysis can show. One may try to avoid the difficulty by saying that it is found by analogy, but that does not really mean anything. Analogy comes in undoubtedly, but in this process analogy is a very slippery guide. There will be a thousand false analogies for one correct one, and no obvious means of choosing them." A great investigator is as individual a genius as a great poet, but, in these days, when dull, rich men really think they can buy scientific discoveries, the point cannot be made too often.

MUSIC, HEALTH, AND CHARACTER.

By AGNES SAVILL, M.D. London: John Lane. 1923. Pp. 234 and index. 7*s*. 6*d*.

AN autobiography of Dr. Savill's musical conversion, to which is appended a discussion of the effects of music on the human organism, forms a most interesting book, one which might be called "From Darkness to Light," or "A Pilgrim's Progress." In the latter part of the book the interest lies in the view of music as a healing agent, taken by a woman physician who has slowly and after various trials been brought to religious faith after a period first of active dislike and later of scepticism. The ground here covered is not, therefore, new, save in its relation to the development of a musical sense. But the first part of the book should be widely read. Those who have and always have had the gift of properly appreciating music will take delight in the upward progress of the musical organism, from embryo to nearly full growth, and those who, to their regret, have no, or almost no, musical faculty, will be heartened in their quest by Dr. Savill's frank revelations of her progress. She tells us how when she was young, and for many years after, music not only bored her but awakened active dislike, not only of the music but also of the performer. In fact, she had much in common with the elder Mr. Osborn, who remarked, "I saw one of 'em speak to a damn fiddler, a feller I despise." Her first awakening came from seeing Maud Allan dance, though the pleasure here was not so much the sound of the music as the rhythmical illustration of it. Then she tried a mechanical piano, but, as was only natural at this stage, found but little pleasure in it, except that it could recall Miss Allan's movements. At last, in March, 1913, she heard Busoni play some Chopin and the light broke in upon her soul. Next she heard Pachmann, of whose playing she gives an admirable description, and before the summer of 1914 she had heard most of the leading pianists of the day, and she adds, "I recall with most delight the fine sensitive beauty of the interpretations given by Mr. Leonard Borwick." She does not tell us what this great artist played, but we hope it was Bach; if so, her musical education was advancing rapidly.

We do not follow Dr. Savill all through her pilgrimage—suffice it to say, that her awakening to orchestral music was brought about by hearing Parsifal. Thence she passed to Beethoven and Bach, to Tschaikovsky, and to some of the moderns, Vaughan Williams, Holst, and Delius. And her opinions and comments upon various composers and their works are of real interest. We do not—no one will—agree with all of them, but her progress so far has been so rapid that we see every reason for supposing that she will attain to the full standard of appreciation. For instance, Tschaikovsky's (6th) Pathetic Symphony has been dethroned from the high seat which it first occupied in her mind, and we venture to suggest that she should hear Nos. 4 and 5, both superior to No. 6. She knows but little of Bach, but realises that his is great music (pp. 100 et seq.) and yet she has apparently heard none of his organ music. To anyone who is able to say, as the author does on p. 208, "Great music arouses a condition of reverence, wonder, and joy, a state of mind similar to that which is produced by prayer, and hence it may be used to bring about the accomplishment of the same high and useful ends," there is a foretaste of the happiness to be gained in the hearing of the Chorale preludes, toccatas, and fugues. The great Toccata in F, with its solemn fugue, is a real musical translation of the twenty-ninth Psalm, and perhaps the most wonderful piece of abstract music ever written is the Dorian Fugue. There is another school of music to which we direct her attention—namely, the polyphonic school of Palestrina, his followers, and the Elizabethan madrigalists. If Dr. Savill learns to understand the Missa Papæ Marcelli (she can hear it at Westminster Cathedral), she will get over her musically youthful admiration of Parsifal.

Dr. Savill confesses that she finds difficulty in distinguishing the various sounds of the orchestra, especially of the wood wind, a difficulty which many others feel. This difficulty is a real bar to the right understanding of music and prevents the hearer from getting much of the good out of music. As a simple and singularly beautiful beginning we advise Dr. Savill to go to hear the B minor Symphony of Schubert, and to take with her a miniature score. In the slow movement is a conversation between flute, oboe, and clarinet, which will aid her to distinguish the respective quality of these instruments, for the score will tell her which is playing. We are in absolute agreement with Dr. Savill's main contention in the second part of her book, which, put shortly, is that good music brings us in touch with the Infinite. Hearing good music, given competent executants, is like talking to great men, for the music is the product of great minds. Of course, even the great composers had their weak moments. Handel wrote a good deal of rubbish, as well as such things as the slow movement at the end of "All we like Sheep," or the Amen Chorus which finishes the "Messiah," or the Allegro movement of the Organ Concerto in G minor in the first set of six, to take only a few of his masterpieces. Even Bach nodded sometimes, but, on the whole, anyone who can hear Bach, Handel, Schubert, Beethoven, Chopin, Palestrina, the Tudor musicians, and Purcell will feel that he is carrying out the apostolic precept, "Whatsoever things are true, whatsoever things are honest, whatsoever things are just, whatsoever things are pure, whatsoever things are lovely, whatsoever things are of good report; if there be any virtue, and if there be any praise, think on these things." That is the frame of mind which helps to maintain a sound body and therein lies the benefit of music in medicine.

Dr. Savill's book is a lighthouse which will, if they look at it, be a guide to many a one who is stretching out his hands in the darkness.

HEALTH AND CONDUCT.

By A. J. BROCK, M.D. Edin., with an Introduction by Prof. PATRICK GEDDES. London: Williams and Norgate. 1923. Pp. 296. 10*s.* 6*d.*

ON p. 285 Dr. Brock asks, "Is the main thesis of this book understood?" and the reviewer has to answer with modesty, "It is not." In such cases light is sometimes to be had from "forewords," but Prof. Geddes's introduction is as obscure as the rest. However, it is clear that Dr. Brock is not satisfied with our world as it is, is persuaded that it needs "sociological re-synthesis and re-orchestration," and that the process of cure is connected in some way with the methods of regional surveys. In medicine he feels that the orchestrator is the general practitioner, to whom specialists should be subordinated, and remarks that there is much less need of further detailed research than there is of our digesting the superabundant information that we already possess—an opinion which will find many supporters. But it is hard to trust an argument which includes the proposition (p. 30) that "the synthetic preparations of the State-supported German drug industry flooded our markets, and were obviously (for the ends of their manufacturers) within sight of controlling our philosophy of life." Perhaps Dr. Brock does not want to say more than that the most important thing in life is one's commonplace daily duty to one's neighbour—which may include giving him a dose of aspirin to help him over a headache; but if that is the message, its form has been insufficiently condensed. Many good qualities have gone to the making of the book, and the author's experience is considerable, but none the less seems to hit no particular mark.

LECTURE NOTES IN MEDICAL PROTOZOOLOGY.

By R. KNOWLES, Major, I.M.S., Protozoologist, Calcutta School of Tropical Medicine. Calcutta: D. N. Banerjee, Banerjee Press. 1923. Pp. 236. 7*s.*

IN these lecture notes, which are arranged as 20 lectures and occupy 236 pages, the author has given a condensed account of those protozoa which parasitise man and the methods by which they are studied. They are not a substitute for lectures, text-books, or practical laboratory instruction, but are intended to serve as a guide to the subject while the student is actually at work. The information is remarkably accurate and practically every important point has been noted. By the use of large type essential facts are emphasised, and warnings against common mistakes are brought to the student's notice. Certain books and papers which may be consulted with advantage are recommended. The student who uses this book as it is intended to be used will find it of the utmost assistance to him, and it will undoubtedly help to simplify a subject which often appears peculiarly confused and difficult to understand.

RUBBER AND GUTTA-PERCHA INJECTIONS.

By CHARLES CONRAD MILLER, M.D. Chicago: Oak Printing and Publishing Co. 1923. $1.75.

THE filling of all cavities in the human body is a difficult problem, and no material has yet been discovered which meets the requirements of every case. Dr. Miller suggests the use of gutta-percha and of rubber in finely divided form, and discusses in some detail the experiments he has tried in the production and manipulation of a suitable filling material. His work is extremely suggestive, but it is a pity that he has given no precise records of either the animal or clinical experiments which he has tried. His methods have scarcely emerged from the laboratory stage, and he concludes by the cautious statement that "for the present patients should be told that these methods are not as yet recognised as established surgical procedures."

The book may be recommended to those who wish to investigate the difficult and important question of filling defects, whether for curative or cosmetic purposes.

The Conduct of Medical Practice.

A Series of Articles by Experts dealing with the Difficulties Encountered in Professional Life and How to Meet Them.

II.—ASSESSMENT FOR INCOME-TAX: DEDUCTIONS, ALLOWANCES, AND RELIEFS.

BY W. R. FAIRBROTHER, F.S.S.,
ACCOUNTANT AND INCOME-TAX SPECIALIST.

For this relief much thanks.—*Hamlet*, Act I., Sc. I.

THE form of account-keeping having been explained in the first article,[1] it is now proposed to deal with the subjects of Income-tax assessment and the deductions, &c., which may be claimed for the purposes of tax.

Computation of Income-tax Assessment.

For the purposes of Income-tax assessment it is permissible to include salaries from public appointments in the assessment on the practice generally. This point was provided for in the preparation of the final account and proves of advantage inasmuch as one demand only is received instead of a number varying with the number of sources of professional income. It is presumed that the final account shows no private payments excepting in so far as it is impracticable to separate them from the business payments. These joint payments would consist of such items as rent, rates, repairs, insurance, lighting, and heating where the practice was conducted from the residence, which is, of course, the general mode of practice. In these circumstances the computation of the profit liable to assessment would be in the following form:—

Balance per account						£1,233	0 0
Add back to profits—							
Half rent (or Sch. "A")			£25	0	0		
Half repairs			5	10	0		
Half lighting and heating			10	0	0		
Half rates, &c.			17	10	0		
Half insurance			1	0	0		
						59	0 0
Adjusted profit for 1922–23						£1,292	0 0

If the practice has begun within the year of assessment (i.e., April 5th), the necessary proportion of the first year's profit will form the first year's assessment; the second year will be a 12 months' proportion of the first year; and the third year will be based on the average of the two preceding years. The fourth and subsequent years' assessments are arrived at on the well-known basis of the three years' average and the calculation of the assessment for 1923–24 would be as follows:—

1922–23—Profit as above	£1,292
1921–22—Adjusted profit previously agreed (say)	1,000
1920–21— ,, ,, ,, ,,	1,000
	3) 3,292
Average for 1923–24	£1,097

It should be mentioned that the proportion of private expenses added back to profit is not uniformly one-half, some districts regarding the proportion liable to be added back as two-thirds. The practice in and about the City of London appears to be to add back one-half, with the result that the other half of such expenses have in effect been allowed as a business charge. Why this practice is not adopted generally (particularly in the provinces) where practitioners conduct their practice from the residence is not easily understood, but it appears to be a point worthy of the attention of medical practitioners' associations. It is, of course, understood that where the premises are used for the practice only, and not for any private or domestic purpose, the whole of the expenses are chargeable.

With regard to the use of a motor-car in the practice a curious anomaly exists. The right to claim car wear

[1] THE LANCET, Jan. 5th, p. 30.

and tear is confined to traders and manufacturers, so that whilst a business man is allowed a deduction for depreciation of the car employed in his business a doctor, whose practice equally necessitates the use of a car, cannot claim the same deduction. The Royal Commission recommended that the allowance should not be restricted to traders, and in this case also there would seem to be scope for pressure by the professional associations to induce the Government to amend the law on the subject. A renewal of a car may, of course, be claimed, but only to the extent of the value replaced less the amount received on sale or exchange.

Deductions, Allowances, and Reliefs.

The amount of the assessment in respect of the business having been arrived at, it becomes necessary to make a complete return on the well-known buff form. The amount liable to assessment should be inserted on page 2, together with any other amounts arising under the other heads shown on that page. On page 3 of the form a complete return of all sources of income and of charges thereon should be furnished to enable the deductions and allowances to be claimed. Page 4 should also be carefully completed so that any allowances may be given against the assessment to be made. The notice of assessment issued later will follow the return made, provided, of course, the latter is correctly completed. On receipt of such notice the assessment amount should be carefully verified together with the appropriate deductions and allowances including earned income relief one-tenth, personal allowance of £135 single, £225 married, and wife to £45 if earning income, child allowance of £36 and each additional £27, housekeeper £45, widowed mother £45, dependent relative £25, first £225 of taxable income at 2*s.* 3*d.*, and life assurance premiums from 2*s.* 3*d.* to 4*s.* 6*d.* per £. The period within which to appeal against the assessment is 21 days, and any necessary notice should be given before that period expires.

There are certain circumstances in which adjustments may be made in the tax payable within or after the end of the year of assessment. The following constitute the principal grounds, and any adjustment can be made to take effect by way of repayment or of reduction in the outstanding tax :—

1. Where a change in ownership has occurred within the year, the current year's assessment is apportioned between the person ceasing and his successor.

2. Where owing to the person ceasing to carry on the profession or dying or becoming bankrupt or from any other specific cause (where ownership has changed) the profit falls short of the assessed amount, a reduction may be claimed to the actual profit of the year.

3. A person succeeding to the practice or a new partnership may apply for adjustment to the actual profit in the year of assessment if such profit is less through some specific cause arising since or by reason of the succession or partnership change. "Specific cause" as referred to here relates to such occurrences as removal to other premises, or loss of personal influence.

4. If the profession has commenced within the last four years a claim may be made for reduction to the actual profit of each year. It is not necessary, therefore, in this period to abide by the average figure and the option of claim is entirely with the taxpayer.

5. If the profession is discontinued, a claim may be made to have the assessment of the current year reduced to the actual profit and a further claim to have the total profit of the three previous years substituted for the total assessments of those years may be entered.

6. Where a loss is sustained in the profession, tax on the amount of such loss is recoverable against any tax paid for that year. This relief is usually claimed only in the absence of any other equivalent relief and then with discrimination, as the loss on which repayment is made is not allowed in reduction of future averages. It is, however, distinctly advantageous to claim when the rate of tax is falling as it can readily be seen that a repayment in, for example, a 5*s.* year, will result in a saving of 6*d.* per £ if the loss is set against a 4*s.* 6*d.* year.

7. In the event of it being found that an error or mistake in the return or statement has been made, repayment may be claimed for three years back on account thereof.

The foregoing points constitute salient features in the taxation of professions, but it will be appreciated that the many phases of assessment and allowances are subject to varying conditions and stipulations impossible of compression into a short article. The many Acts and various text-books on the subject of Income-tax readily demonstrate the complexity of modern taxation, and probably no field in the fabric of social life is so encumbered with legislative enactments and judicial decisions, not to mention the numerous modifications introduced in practice. The ramifications of taxation are so wide and so deep that even in an extensive practice it is an almost unique occurrence to deal with two cases containing precisely similar circumstances and conditions. It is true that members of any one profession may derive help in conforming generally to an approximately standard type of business assessment—as shown above—but it is equally true that in the computation of other income, in the statement of charges, and in the claiming of adjustments and allowances they must join the general community of confused and exasperated persons known as "taxpayers."

THE DISCOVERY OF RADIUM.

CELEBRATION IN PARIS OF THE TWENTY-FIFTH ANNIVERSARY.

IT is now just over 25 years ago that (on Dec. 26th, 1898) the discovery of radium was made known to the scientific world in a communication addressed to the Académie des Sciences de Paris. On Jan. 2nd two ceremonies took place, one at the Fondation Curie, the other at the Sorbonne, in celebration of this anniversary. The first of these was the inauguration, in the presence of Mr. Paul Strauss, Minister of Hygiene, of the Dispensary of the Fondation Curie; at this ceremony many leading scientific and medical men took part. Mr. P. Appell, Rector of the University of Paris and president of the Council of Administration of the Fondation, opened the proceedings; orations were then delivered by Mr. Régaud, professor at the Institut Pasteur and secretary-general of the Fondation, by Mr. Bergonié, and by Mr. Strauss, who expressed to all those associated with the Fondation, and particularly to Madame Curie, the recognition by the Government and the public of the great results obtained in the incessant work carried on by the institution.

At the second ceremony, in the great amphitheatre of the Sorbonne, the chair was taken by Mr. Alexandre Millerand, President of the French Republic, who had on his right Mme. Curie. Mr. Appell, speaking in the name of the Fondation Curie, described the achievements of science made possible by the great discovery associated with the names of Mr. and Mme. Curie, thanked the President and the representatives of Great Britain, the United States, Belgium, Spain, and other countries for their presence and support, and paid a tribute to Mr. Strauss for his organisation of regional centres for the campaign against cancer. He concluded his address by expressing the gratitude of the Fondation to Mme. Curie for her gift of a gramme of radium, to Mr. Henri de Rothschild for his recent donation of 500 milligrammes of the element, and to other benefactors of the institution.

Mr. Jean Perrin gave a brief survey of the importance of radio-activity, and Mr. Baclère dealt with the relations of radium and medicine. Mr. Léon Bérard, Minister of Public Instruction and Fine Arts, recalled the circumstances in which was passed the Act recording the discovery of radium, and expressing the gratitude and admiration of the Republic upon that occasion. Mme. Curie briefly replied, and the President associated her name with that of her husband in a final tribute of praise.

THE LANCET.

LONDON: SATURDAY, JANUARY 12, 1924.

ORGANISED MEDICAL RESEARCH.

THE report of the Medical Research Council for the year 1922–23, which is published to-day,[1] records the retirement from the Council of Sir WILLIAM LEISHMAN and Prof. F. GOWLAND HOPKINS, the two last remaining members of those originally selected in 1913. They have thus served the Council over a period of ten years, and this report is to some extent the record of a decade of organised medical research, for a number of the objects of present study were among the earliest schemes of work. Tuberculosis was one of these early objects, as was natural when the research fund was obtained from National Insurance resources by a levy of one penny per insured person.

The Council is no longer directly related to the Ministry of Health, but tuberculosis work continues to be directed by a group of subcommittees to which, by permission of the Ministry, Dr. A. S. MACNALTY acts as secretary. One subcommittee deals with bacteriological questions, another with the uses of tuberculin, while statistical studies are supervised by a Statistics Committee which includes other aspects of industrial health. A special subcommittee is in charge of the trials now being made with Prof. G. DREYER'S diaplyte vaccine. Heliotherapy comes within the scope of the Committee on the Biological Actions of Light. The personnel of all these committees is set out in the document, and we call attention to them as one example out of many of how the work of the Council has broadened and ramified during ten crowded years. The subject of accessory food factors, one of a group which sprang into importance in the critical years of war, continues to occupy the close attention of a committee appointed jointly by the Council and the Lister Institute. The work of Dr. HARRIETTE CHICK and her colleagues has modified the continental conception of rickets as an infectious disease and popularised the idea of vitamin deficiency which, nebulous though it still is, may prove a boon not only to the starving Viennese children who were the first to benefit. This war-time work has carried on into the post-war period which has provided many new activities of its own. Most dramatic of these was the overdue discovery of the function of the pancreatic islands by the Toronto school, since enriched by the work of Dr. H. W. DUDLEY and Dr. J. H. BURN at the Central Research Institute—work which is justifying Dr. H. H. DALE'S prophecy that insulin will prove to have an importance for physiology and medical science far beyond that of its use in the treatment of diabetes. These three examples, taken from different periods, will give an idea—it is impossible to do more—of the volume of organised research which increases from year to year.

A contribution of £130,000 is the sum-total allotted to medical research by a country of business men, and it is almost incredible how this sum has gone so far. It includes the expenses of the Industrial Fatigue Research Board, for which the Council became sponsor rather than allow its work to drop. The National Institute, the central forcing-house, absorbs about one-third of the remainder, and yet nearly 600 entries appear in the index of personal names of associate workers. Many of these are nursing seedlings which are still in cold frames, but there is more than a chance that some of them will prove hardy enough to survive, although no one can say which. One can only hope that the scientific zeal of the individual is not being unfairly exploited by the community, a suspicion raised rather than allayed by the Lord President of the Council when he stated recently that many men of science would work for Government at less remuneration than similar private work would receive. A closer study of the Research Council's finance is reassuring, for the Council is becoming increasingly a clearing-house for research funds. The Dental Board has allotted a large sum for inquiry into the causes of dental disorder, the Miners' Welfare Fund another for studies of miners' dietaries, the Carnegie Trust a third for investigation of environment on the growth of children. These and other grants from various sources, including relatives of grateful patients, are placed at the disposal of the Council. Moreover, the Rockefeller Foundation has made it possible to give a group of British workers the opportunity of scientific study in the United States besides sending American students here. The proper outlook of research is dealt with in a few striking paragraphs of the report. It is something other than that of the "man of science," so humorously ridiculed by Sir RONALD ROSS, as the sort of person who pulls out his watch and exclaims: "Ha! half an hour to spare before dinner: I will just step down to my laboratory and make a discovery." The bearing of much research work upon medicine and hygiene necessarily seems remote, but the history of insulin—even the name of which was suggested many years ago by Sir E. SHARPEY SCHAFER—is a complete justification of the wide view. And it is the wide view that must be popularised, for many can appreciate results who cannot follow the intensive studies which have led up to them.

[1] Committee of the Privy Council for Medical Research. H.M. Stationery Office. 3*s.* 6*d.*

FOOT-AND-MOUTH DISEASE.

HUMAN medicine is not greatly interested directly in the epizoötic stomatitis of animals, for it is a fact, as the Minister of Health recently stated, that foot-and-mouth disease is rarely communicated from animals to man, and, when so communicated, the illness has been mild; in this country there is no record of death having resulted in a healthy person. Moreover, the use of milk from infected animals is prohibited by law, and the enforcement of this regulation is not very difficult. But the epidemic of this cattle plague which is at present visiting the country presents problems very interesting indeed to the medical man; for here is an epidemic against which the most effective methods can be used, whatever they may be. Endemic small-pox or plague cannot be stamped out by simply destroying the centres of infection, but the Ministry of Agriculture has public opinion solidly behind it in attempting so to stamp out foot-and-mouth disease if the procedure can be justified economically. Up to the end of last week more than two millions of money had been laid out in compensation for destroyed animals, something over a quarter of a million being returned in the salvage of healthy carcasses. The total number of animals then condemned amounted roughly to 68,000 cattle, 25,000 sheep, 33,000 pigs, and a few goats. At the same time, hunting has practically stopped, and hunting is an industry as well as a sport, providing a weekly sum of £75,000 in wages and £175,000 a week in forage. Further, the risk of infection has led Australia to prohibit the

importation of cattle, sheep, swine, and goats from Great Britain or Ireland, the Union of South Africa has done the same, while the Free State of Ireland, after forbidding the import of animals and poultry from infected areas in Great Britain, issued a still stiffer order on the first day of 1924. Whichever way the nation turns there is fearful loss to contemplate, unless the policy of slaughter is rapidly successful.

On the epidemiological side the problem touches human medicine very closely, for is not the infection of epizoötic stomatitis of the same order as that of influenza or measles? It was proved during the last years of last century—by LÖFFLER and FROSCH, by HECKER, and by NOCARD and ROUX—that the virus will pass through fine filters. The virus is present in the blood-stream of affected animals in the early stages of the disease, and is found abundantly in the lymph of the characteristic vesicles and in the saliva. From these situations, however, it soon disappears. Recovery from the disease is the rule, but the immunity which is left is generally short-lived. In the average case, an animal which has passed through an attack is refractory to a second infection for about a year, but cases are not infrequent where a second infection follows within a period of a few weeks. The attempts which have been made to confer immunity have been partially successful. The possibility of passive immunisation of cattle with highly potent serum has been shown by NOCARD, ROUX, CARRÉE, and VALLÉE. An immune serum is obtained from cattle which have passed through an attack of the disease, or from cattle which have been hyper-immunised. Active immunisation is attained by injecting an animal first with immune blood and then with virus which is obtained from infective lymph or blood. The volume of blood required to confer passive immunity depends, of course, upon the potency of the blood injected. This, as a rule, is low, and the quantity required may be as much as 500 c.cm.—a fact which prohibits the application of the method in the field. Moreover, since it has been found by VALLÉE and CARRÉE that there exist more than one strain of virus, it is clear that a polyvalent serum would be required. Attempts to cultivate the virus have been made by many bacteriologists in France and in Germany, but so far without success. The isolation and easy cultivation of the virus is, however, clearly the first and most pressing need. Given a regular supply of virus, the immunity work would be simplified, and the possibility of prophylactic vaccination would be before us. Further, an accurate and precise knowledge of the virus would be of immense value to those who are engaged in attempting to discover the mode of spread of the disease—work of the first importance for this country. But here lies a grave difficulty which has apparently escaped the attention of the daily press in its almost petulant demand that something shall be done. It is simply impossible in the present circumstances for an individual bacteriologist or for any institute of research to undertake such work. The necessarily stringent regulations which aim at eliminating foot-and-mouth disease prevent this, and for the obvious reason that the authorities fear the possibility of the disease spreading from laboratories engaged in the research. Moreover, the expense of such work would be too heavy for the slender resources of any laboratory in this country. An attempt to cultivate the virus of foot-and-mouth disease would need official permission in the first place, and in the second place considerable public financial assistance. These granted, is the problem a fit one for investigation, and if so, what could reasonably be done?

The first of these questions deserves notice. The unprinted, though freely spoken, objections to the initiation of research are: First, that the problem of foot-and-mouth disease has been studied abroad during the last 20 years and without conspicuous success, and is therefore, if not insoluble, too difficult for profitable inquiry; and, secondly, that it is impossible to study the disease in this country because of the risk of spreading infection. The first objection may be dismissed: if this spirit prevailed in medicine there would be no research on cancer or, indeed, on any of the outstanding pathological problems. Medical knowledge would stagnate, and the profession would merit the contempt of enlightened men. The second objection has, if newspaper reports are correct, been answered by the veterinary experts of the Board of Agriculture. Pedigree herds of cattle which have been affected have been spared because the conditions under which the animals are kept, and the strict isolation of the farms on which the disease has occurred, are such that infection cannot spread. It can hardly be beyond the wit of man to plan an experimental farm at least as well situated and controlled as these.

In order to answer the second question—namely, what are the prospects of success in the search for the virus—we must be guided by what is already known of the class of organisms which are called "filter-passers." The human diseases which are known to be caused by filter-passing viruses have been extensively studied, particularly by the Rockefeller Institute in New York. The virus of infantile paralysis has been grown, and within the last three years OLITSKY and GATES have described a small organism, the *B. pneumosintes*, which they believe to be the cause of influenza. The difficulty with most of the human diseases lies in the proof that any given organism is the causal organism sought. We are compelled to resort to animal tests, and the lower animals are not as a rule susceptible to the disease under investigation. If the medical clinician has an advantage over his veterinary colleagues, the balance of advantage is more than redressed for the veterinary bacteriologist. In pleuro-pneumonia of cattle an exceedingly small coccus, just within the range of visibility of a good microscope, has been isolated in pure culture. The coccus grows readily on suitable solid media in minute colonies, and has been proved to be the causal organism by animal experiment. In this instance we have the one definitely successful culture of a filter-passing virus. Can the same success be achieved for foot-and-mouth disease? Maybe the coccus of pleuro-pneumonia is easier to grow than other filter-passers, but this cannot be affirmed until the attempt has been made. The technical procedure which is most in favour at the present time is that devised by THEOBALD SMITH and modified by NOGUCHI. The essential principle of the method is the employment of fresh tissue—usually kidney—a small piece of which is dropped into nutrient fluid. The medium thus produced is anaerobic and is suitable for the rapid cultivation of the ordinary large anaerobic bacteria. Coincident with the growth of an organism a haze develops, usually in the vicinity of the tissue, and this is transferred to another tube of the same medium in the ordinary process of subculture. Subsidiary lines of investigation consist in attempts to stain an organism or to examine the fluid medium under the dark-ground microscope. But the results obtained by such methods are generally unsatisfactory owing to the confusion produced by the occurrence of large numbers of particles which arise in the disintegration

of the tissue in the tube. The final and satisfactory proof that a living organism has been grown in such a liquid medium depends upon the successful production in series of definite colonies on solid media; and the proof that a pathogenic organism has been grown depends upon the successful reproduction of the disease under investigation in a susceptible animal by a remote subculture. The successes already gained in the study of filtrable viruses warrant us to be hopeful as to the outcome of an attempt to isolate the organism of foot-and-mouth disease. If there is any valid objection to such work being undertaken, it is on the ground of expense. It would be unwise to be driven into foolish or costly experiments; but when the present epidemic has died away, let us not fall into complacency.

ALCOHOLISM AND SOCIAL CLASSIFICATION.

WE publish elsewhere (p. 109) an abstract of a paper read last Tuesday before the Society for the Study of Inebriety by Dr. H. M. VERNON, in which he draws some valuable conclusions upon the factors concerned in the promotion and prevention of alcoholism, and in its incidence upon various classes of society, as displayed in the seventy-fifth annual report of the Registrar-General. This report relates to the period 1910–12, and the part played in the decline of consumption by high taxation or the reduced hours of sale is, therefore, not under consideration; but the information, and the deductions to which it gives rise, are none the less useful to all medical men, while the subject is treated by Dr. VERNON with the accuracy and suggestiveness that we should anticipate from one whose writings upon industrial efficiency and the related influence of fatigue have already given medicine so much to think about.

Dr. VERNON has simplified the classification of the Registrar-General by considering under one heading the five groups which can be described as "skilled and semi-skilled workmen," placing those engaged in the production and sale of alcohol in a separate category, while occupational groups, where the number of deaths from alcoholism and cirrhosis of the liver were very small, have been ignored, to the prejudice of certain more abstemious sections, but the effect of any error of judgment is annulled by the acknowledgment of the omission. The data relate to males between the ages of 25 and 65, and by comprising in one group all skilled and semi-skilled workmen the classes to be considered fall under five headings—namely: (1) this large combined group; (2) unskilled workmen; (3) professional classes; (4) shopkeepers; and (5) brewers and publicans. It is found that expressed as a percentage of a general mortality the alcohol mortality in all five is practically constant; for example, in the first group, with a comparative general mortality of under 600, there is an alcohol mortality of 7, while the next division had a comparative general mortality between 600 and 700, with an alcohol mortality of 10, and in succeeding divisions the alcohol mortality increased as the general mortality increased, save where the employees in the liquor trade manifested a worse rate. To show fully the significance of the correspondence between the two sets of figures it would be necessary to ascertain to what extent the general mortality is affected by alcoholic indulgence, and here certain evidence is obtained by comparing the cause of death in typical groups of individuals liable to indulgence with other groups not so liable, but otherwise of similar environment. Comparison has been made between the group whose members are engaged in the production and sale of liquor and the group classed as shopkeepers, which comprises drapers, grocers, butchers, greengrocers, ironmongers, chemists, and tobacconists. A tabular statement was given by Dr. VERNON recording the mortalities of the two groups from various diseases, when under each heading the mortality among the publicans was higher, whilst their mortality from alcoholism was vastly more sinister.

A distinct warning is given in Dr. VERNON'S paper that we must look elsewhere than to alcohol to account for the larger part of the variations in the general mortality of industrial workers. Those who work in the open air, as the Derbyshire coal-miner, those who work usually under cover, as the sawyer or the coach-builder, have their differences of environment, but in neither case are they subjected to the conditions which prevail in factory work with artificial heating; and among the coal-miners the mortality is low except from accidents, for although they are working underground and at high temperatures, there is circulation of air in the pits. Other groups of workers, as railway guards, bricklayers, ship-builders, give evidence of the importance of fresh air; and while the general mortality rises the moment we are dealing with typical indoor workers, such as cabinet-makers, boiler-makers, or printers, it is higher still among the group engaged in iron and steel manufacture, pulmonary conditions exacerbated by exposure after overheating playing their rôle. The section with the highest mortality includes those exposed to dust inhalation, and those who, like the Lancashire coal-miners and operatives in glass manufacture, work in excessive temperatures. And the general lesson is that the relationship between the alcohol mortality and the general mortality of industrial workers is constant, but different from that among those engaged in the liquor trade. A division with a low comparative general mortality comprises medical men, lawyers, and artists. Here the alcohol mortality is higher than among industrial workers. The far higher alcoholic content of spirits over beer explains the discrepancy, but not the tendency towards indulgence which is displayed in a section of the community possessing full knowledge of its dangers.

THE PANEL INQUIRY.

THE Court of Inquiry appointed by the Minister of Health to determine the capitation fee to be paid to insurance practitioners during the year 1924 held three public sessions on Friday, Jan. 4th, and Monday and Tuesday, Jan. 7th and 8th. On the first day the case for the doctors was set forth in evidence by Dr. H. B. Brackenbury in amplification of the printed document drawn up by the Insurance Acts Committee. Dr. Alfred Cox and Prof. A. L. Bowley giving corroborative figures. Dr. Gordon R. Ward made a statement on behalf of the Medical Practitioners' Union. The case for the Ministry of Health and the Scottish Board occupied the remainder of the Friday and all the Monday session. A report of the proceedings of these two days appears on p. 97. On Tuesday evidence was given on behalf of the National Association of Assurance Committees mainly by the President, Rev. W. D. Yoward, M.A., and the Hon. Secretary, Mr. Edwin Potts, and the Ministry of Health replied, the final word being with Dr. Brackenbury. The Court will sit again on Tuesday, Jan. 15th, to hear the case presented by certain independent approved societies, their main case being reserved for a session on Jan. 21st. We hope next week to report two further sessions. All that need be said at present is that the proceedings of the Court were of a harmonious nature and the impression was given to all parties of a fair and courteous hearing.

Annotations.

"Ne quid nimis."

PUBLIC HEALTH WORK AT THE LEAGUE OF NATIONS.

THE Council of the League of Nations at its session in Paris last month decided on the names of the six medical members of the new Health Committee of the League who were required to supplement those who had already been nominated by the Office International d'Hygiène Publique. The six members thus chosen were Dr. Th. Madsen (Denmark), who has been President of the provisional Health Committee of the League since 1921, Prof. Léon Bernard (France), Prof. Ottolengli (Italy), Dr. J. Jitta (Holland), Dr. Pittaluga (Spain), and Dr. Chagas (Brazil). The members already appointed by the Office International d'Hygiène Publique were its President, Mr. O. Velghe (Belgium), Dr. Raynaud (France), Sir G. Buchanan (Great Britain), Dr. Lutrario (Italy), Surgeon-General H. Cumming (United States), Dr. A. Granville Pasha (Egypt), Prof. Ricardo Jorge (Portugal), Dr. H. Carrière (Switzerland), and Dr. Mimbela (Peru), an additional nomination for a medical representative of Japan being left open. The constitution of the Health Committee of the League provides for only 16 members in the first instance, but the Council recommended the Committee to add to itself two other nominees, Prof. Nocht, of Hamburg, and Dr. Chodzko, late Minister of Health at Warsaw, who represented Germany and Poland respectively on the former organisation.

The membership of the new Committee, which is appointed for three years, is distinguished and influential. It may, however, be objected that its personnel is too exclusively derived from the official public health services of the countries concerned, consisting as it does so largely of Government delegates of those countries to the older international office. This circumstance, however, follows naturally from the fact that the activities of the League of Nations in health matters must in the main be carried on through the government public health services of the world which the older office represents. It may be recalled that under its new constitution the Health Committee of the League is expected to act when necessary through special committees on which experts on particular subjects have been co-opted, and it may be anticipated that this practice will be extensively followed. A more serious and obvious criticism is that on the basis of representation by countries no place is found in the present list for any member of the important public health services of India, of the several British Dominions, or of British colonies. Steps should be taken, with as little delay as possible, to rectify this omission from the constitution of a body which demands, and has hitherto received, welcome participation from all parts of the British Empire. The Health Committee will hold its first session under its new constitution at Geneva in the course of February, when reports of the League's commissions on quarantine measures in the Far East, on the unification of standards for therapeutic sera and of serological tests, on the opium traffic, on standardisation of "biological" remedies, and on international comparisons of cancer mortality will be taken. The Office International d'Hygiène Publique at Paris now acts officially as the advisory health council of the League, and at its regular sessions will in future have an account of the work of the Health Committee of the League before it for consideration, and the opportunity of making proposals for increasing the usefulness of the League's organisation for promoting international measures of public health.

A summary of the work of the last session of the permanent committee of the Paris office was included in the November number of the monthly bulletin of the Office International. In addition to the settlement of matters affecting its future as an advisory body to the League of Nations, while remaining otherwise autonomous, the delegates decided on the final text of the international nomenclature of causes of death, which had been left in doubt owing to the death of Mr. J. Bertillon. They established the existence of a wide difference of expert and administrative opinion on the American proposal that heroin should be prohibited for medical purposes, and settled the form of the proposals to be made to the Governments represented regarding international agreements relating to the composition of anti-diphtheritic serum and the adoption of a uniform pattern of Bill of Health for shipping purposes.

TUBERCLE IN THE FRENCH ARMY.

THE *Archives* of Military Medicine, which is the official journal of the French Army Medical Corps, devoted its last number (vol. lxxix., No. 1) wholly to the consideration of tuberculosis in the army, the chief paper being a long and careful discussion of the question from the practised pen of Médecin-principal M. J. L. R. A. Jeandidier, who with all his study is not very hopeful. He concludes that tuberculosis in the army only reflects the conditions of civil life, the morbidity being lessened, however, in the army by the selection which goes on when the recruits come up to join. What, then, is doing in civil life to get rid of this plague? We cannot destroy the infection; vaccinations have so far failed; now we are trusting that if we ward off massive infections, the small doses that will be received will set up a relative immunity. "Unable as yet to prevent tubercle," Colonel Jeandidier puts it, "we await protection by universal tuberculinisation." The army might be protected by the exclusion of all possibly unsound recruits, but that weapon is blunted from the start, for France, though she has only a small population, needs a large army. Hence the army cannot get rid of this scourge, but can only lessen it. This it can do in several ways: (1) In liaison with civil agencies; (2) by giving anti-tuberculous instruction to the soldier in barracks, not only to the sick in hospital; (3) by early diagnosis, and swift isolation and discharge of the infected; (4) by making selection as careful as possible at entry; (5) by constant, assiduous observation of the doubtful whom the army has to receive; (6) by strict application of hygienic measures; methodised training; sufficient, varied, and well-cooked food, healthy housing, sufficient warming, enough clothing, good medical treatment. But having enumerated all these points Colonel Jeandidier comes back again to the basic fact that since a definite number of recruits are required every year, they cannot be obtained if all the suspicious are excluded; so far the balance has been found from colonial troops, themselves very susceptible to tubercle. The alternative—namely, long service for sound men—is too expensive. Every hygienic measure means more expense, for the new watchword "Selection and hygiene" is just the familiar "Men and money." Can they be found? Or must it be admitted that the watch-dog costs so much that the house must be left open to the thieves? Colonel Jeandidier leaves it at that.

CHRONIC ULCERATIVE COLITIS IN CHILDREN.

IN a paper read before the last annual meeting of the American Pediatric Society, Dr. Henry F. Helmholz,[1] of the Mayo Clinic, has recorded five cases of chronic ulcerative colitis in children aged from 8 to 15 years. Four of the cases had been under his own observation, and one had already been published by Logan, who in 1919 had defined the condition as a chronic inflammation of the large bowel of unknown ætiology, and showing all grades of inflammation from a reddened, congested, easily bleeding

[1] American Journal of Diseases of Children, November, 1923.

mucous membrane to superficial and deep ulceration with constant or recurring dysentery lasting from many months to several years. In none of Dr. Helmholz's cases was it possible to demonstrate the presence of any pyogenic, dysenteric, amœbic, or tuberculous infection. In four cases the colitis started acutely with a bloody diarrhœa, and in only one instance was the condition chronic and not accompanied by diarrhœa. The ulceration begins in the lower part of the bowel, and in the course of the illness the entire colon is involved. The ileum is rarely affected. On proctoscopic examination the ulcers are usually most marked in the rectum and lower part of the sigmoid. The colon as a rule is thickened. In severe cases only small islands of normal tissue are left, the entire surface being ulcerated and presenting a granular appearance. X rays show marked narrowing and absence of haustrations of the colon. The stools are usually five to ten in number daily, and contain a considerable amount of muco-pus and blood, frequently in clots. If there are no complications the temperature is usually not raised. Acute arthritis, which is frequent in adults, was seen in only one of the present series. The diagnosis is based on the occurrence of muco-purulent diarrhœa, with the passage of considerable amounts of blood, usually in clots, the persistence of the dysentery in spite of all medical treatment, and the absence of any of the usual ætiological factors. The prognosis under medical treatment is bad, as was illustrated in the present series of cases which did not show any improvement until after surgical intervention. The operation of choice is Brown's method, which consists of an ileostomy, with the establishment of a complete fæcal fistula through which the colon can be irrigated.

FOCAL SEPSIS.

NOT the least useful of the functions performed by a medical congress is that of concentrating general attention on the more outstanding problems of the moment. This was reflected at the recent Australasian Medical Congress of the British Medical Association in Melbourne, the first of its kind ever held in Australasia, which covered six days, and was concluded on Saturday, Nov. 17th. One of the most interesting discussions was that on Friday afternoon, dealing with focal infection in relation to general disease. Dr. R. Scot Skirving, of Sydney, who opened the discussion, urged that all definite septic foci should be treated by radical removal, whether they were thought to be responsible for general disease or not, a conclusion with which it is difficult to quarrel; but the scanty nature of the evidence linking such foci as dental abscesses even with diseases such as rheumatoid arthritis and pernicious anæmia was rightly emphasised by several subsequent speakers, including Prof. A. E. Mills, of Sydney, and Dr. S. O. Cowen, of Melbourne. In our last issue we reported a discussion on pneumococcal infections which took place at the meeting of the Manchester Pathological Society on Dec. 12th, Dr. J. H. Dible's opening paper appearing in full in the same number. The opinion of the pathologists, including Profs. Shaw Dunn and Matthew Stewart, appears to be trending strongly towards the view that such infections are more often due to local spread than has hitherto been believed. Dr. Dible in his concluding remarks crystallised such belief by saying that he felt that the hæmatogenous theory of invasion had been overthrown in two of the chief pneumonic infections, and that bacteriologists as a whole realised that the blood in most bacterial infections was well able to look after itself.

The whole theory of the responsibility of oral, pharyngeal, and intestinal sepsis for general arthritis, anæmia, gastric and duodenal ulceration, dermatitis, and a host of other diseases, still rests upon the flimsiest of bases. The experimental studies[1] of E. C. Rosenow, which at first appeared to throw a flood of light on many pathological problems of magnitude, have, as far as we are aware, never been adequately confirmed. Lord Dawson, speaking from the chair of the Medical Society of London, referred some 12 months ago to the importance of this omission. Rosenow's work seemed to show that streptococci, cultivated from the septic teeth of a patient with gastric ulcer, would, on injection, often produce such ulcers in rabbits. This, and many similar observations by the same worker, seemed to supply the long-sought evidence. Published in 1919, the experiments are not yet accepted by the majority of pathologists. At the same time there is no ground for entire scepticism on the subject. The Wassermann reaction gives us evidence of a general infection from a small primary syphilitic sore, which it would be impossible to obtain otherwise. Yet Prof. Fourneau, of the Pasteur Institute, has been able to synthesise a drug which, taken orally, will prevent syphilitic infection in human beings or monkeys when the spironema is inoculated into a skin lesion. This is the latest result of a belief in the relation of general to local infection which is clearly sound though not based upon microscopic bacteriological evidence.

The consolidation of the dental profession presents a fitting occasion for a more thorough investigation of the problem of focal microbic infections, and we suggest that, in view of the importance of the subject, the Ministry of Health would be well advised to organise a complete inquiry into the matter.

"THE KIND OF NURSE SHE WANTS."

A LETTER with this heading was published in our issue of Dec. 1st, 1923, from a writer who complained that the employment of trained nurses was very embarrassing to small householders, and indicated that there were many illnesses where the patient only needed "someone to wash me, to bring me my food, to make my bed, and in fact to attend to my physical needs" for which services a trained nurse was not required. The writer gave expression to a really great public need, but made no suggestion how it should be met, and we confess that our own position is somewhat similar. Once again we have an example of social progress where in the course of the progress certain of the old amenities are lost.

For the last 40 or 50 years the whole course of opinion, we may say of civilisation, has tended to develop a nurse highly educated in theory and highly trained in practice. Such a nurse can be trusted not only to take the patient's temperature and pulse, to keep an accurate note of excretions, and to make simple analyses, but also to record with intelligent comprehension much clinical observation. Further, the modern nurse is familiar with the details of aseptic surgery, and thoroughly capable to assist a surgeon in a difficult operation This highly finished product is valuable, is properly aware of the fact, and has developed a sense of professional self-respect. For the cases that need her she is exactly what is needed. But for the writer of the letter in our columns she is not "the kind of nurse she wants." And where serious sickness is not in question the position and capacities of the modern-trained nurse may prove an embarrassment, especially if she be without tact. She is herself well educated in her own subject, but often ignorant of the world from other points of view, owing to the semi-conventual life of a hospital, although we believe this is less so than a few years ago. She may find herself unwelcome in a house, and be aware that her emolument is adding to the cost of an already expensive illness. Her ways are not the ways of her employers, any more than her people are their people. And employers are often selfish and tactless, when the illness is not one where every detail in the life of the household has to be subordinated to the claims of the sick and the sick-nurse.

It is not, therefore, a matter of wonder if those who are invalids rather than acutely ill, should desire

some simpler and less expensive attendance than is given by a trained nurse, while it seems clear that it is not from a trained nurse they should expect it. Those who are in the situation of our correspondent really want a domestic servant with some knowledge of nursing routine such as might be picked up by a brief sojourn at a cottage hospital. In three months a lady's maid, an intelligent parlour-maid, or a housemaid might be given enough training to make her a valuable adjuvant to the patient and the doctor in cases of invalidism. Fifty years ago such patients were always nursed in this manner; they were saved both from strange hands and strange ways, and from the heavy expense attendant thereon. Is it possible that a system should arise whereby a class of nursing-maid could be created? Or must any attempt to organise such a grade of nurses mean underselling the existing highly qualified service, with some risk of putting a premium on ignorance? In America the Rockefeller Foundation definitely advises the creation of a nurse of this simpler kind. It proposes that she shall have about nine months of training and be registered in her own class. Anything like a second register in this country would be opposed on general lines as retrograde, and a letter from Miss Muriel Payne, in our issue of Dec. 29th, shows that this apprehension has grounds. Nevertheless the suggestion has been made of making a register of handywomen who are not qualified midwives, and this dual scheme of maternity helps has the support of the Ministry of Health. But apart from a definite register of nursing-maids, use might be made of certificates from the cottage hospitals. The district nurse is not in question. She is a fully trained nurse who has specialised in house-to-house work after certification. She would be one of the very best agents for sanitary education in the kingdom if the county authorities had their eyes open, and if the public had learned to appreciate her rôle, and it is certain that in course of time she will come into her own. But she is not fitted for the work now under consideration. If any organised body could produce the requisite article it would probably be one of the Cottage Nurses' Associations. They might, if there was a demand, supply the kind of nurse required, or even, as in other industries, create the demand by offering the supply. That there is considerable need of some such nursing we have no doubt at all, but at present neither the demand nor the supply is organised.

INSECT PESTS.

MAN is so sure that he is the only live thing which matters very much that he is always quite ready to urge that if bacteria are not the most important group insects certainly are. And the recent progress of knowledge has emphasised the parts played by them in all sorts of directions centring round human activities and interests; the species of insects are so numerous that it is little wonder that they do a great variety of different things and turn up in one form or another almost everywhere. Mr. R. A. Wardle and Mr. P. Buckle have put together a most interesting survey[1] of the methods which are available for keeping insects within reasonable bounds. For the most part the authors deal with insects in relation to vegetable crops, and it is interesting to notice how the cultivation of great quantities of the same plant in an area has brought pests into prominence. This is due, no doubt, partly to the demand for a higher standard of healthiness by the cultivator, and finds its parallel in the refinement in human beings which has come to call the common cold a "disease." But it may be attributed mostly to the effect of aggregating large populations together and giving the parasites a larger field to work over in their business of breeding out virulent races. It is when the give and take of natural conditions is artificially broken up that parasites get their real chances; market gardening on the modern scale has much the same effects as compulsory elementary education and urbanisation in general. And the problem in this particular branch of economic entomology is just the same as confronted the early human sanitarians, such as Chadwick, whose portrait Mr. Lewis has been exhibiting so effectively in Oxford-street. Along lines such as these the whole problem of the control of plant pests is of great interest to anyone concerned with human hygiene; the parallels and differences might profitably be discussed by both groups of workers, for each will get help from the other. The items of immediate medical interest are not treated at all fully; mosquitoes receive some attention, but fleas and bugs are mentioned only casually and *Glossina* apparently not at all; lice and ticks are dealt with in more detail. Domestically, several methods are noted for cockroaches, but the only reference to furniture beetles is a mention of the thermal death point. The book does not, indeed, purport to be an exhaustive encyclopædia of what has become a vast subject; and it is better that it should not be so. Though it is not very well written and the paragraphing is bad, in its present form it will afford interesting and suggestive reading to many people who are not immediately concerned with agriculture at all, and the ample bibliography at the end suggests how easy it would be to follow up any particular point.

[1] The Principles of Insect Control. By R. A. Wardle, M.Sc., Lecturer in Economic Zoology in the University of Manchester, and P. Buckle, M.Sc., Lecturer in Agricultural Zoology in the University of Durham. Manchester: University Press. 1923. Pp. 295. 20*s*.

TWO ROCKEFELLER GRANTS TO CLINICAL MEDICINE.

AT the end of last year announcement was made of two substantial donations by the Rockefeller Foundation towards clinical teaching in Great Britain. Some details of the Edinburgh grant were given by our Scottish correspondent in our issue of Dec. 29th. It had been recognised for some time that the facilities for clinical research and for advanced teaching in both medicine and surgery were not adequate for a school with the reputation of Edinburgh, and it was in order to meet this need in some degree that the grant was made. Of the total sum of £50,000, £33,000 are to go towards the building and £2000 towards the equipment of a medical clinical laboratory. In order that the director of the laboratory may be free to devote himself to this development, a further grant of £1000 per annum has been made for five years to supplement his salary and that of his staff, and to enable him to make necessary additions to his staff. As regards surgery, it is planned to unite the two existing chairs of systematic surgery and of clinical surgery under one whole-time professor, and, subject to the completion of these plans, a sum of £15,000 will be applied to augment the endowment, so that the salary of the professor may be approximately £2000. The remaining sum of £750 for five years will be available for additional salaries rendered necessary under the scheme.

In making a donation of £14,000 to the Welsh National School of Medicine the Rockefeller Trustees warmly approved the ideal of a National College of Medicine for the whole of Wales, and the adoption of the unit system of teaching in the final years of medical study. Two other factors which, we understand, influenced the Trustees in their decision were the public-spirited response of local authorities in Wales to the recent appeal on behalf of the medical school—the product of one-eighth of a penny rate was conceded—and the fact that the Cardiff Royal Infirmary has now allocated the minimum number of beds needed for a medical unit. The gift is regarded as a landmark in the history of the medical school and is worth far more than its mere monetary value. The prestige attached to recognition by the Rockefeller Foundation will be of particular benefit to a school which has taken such a definite line of its own in medical education.

CARCINOMA OF LINGUAL THYROID.

ACCORDING to Dr. Albert F. Tyler,[1] of the Department of Roentgenology, John A. Creighton Medical College, Omaha, who reports an illustrative case, the term "lingual thyroid" is applied to a tumour in the root of the tongue due to failure of the thyroid to migrate to its normal position during embryonic development. The condition was first described in 1853 by Vernueil, who discovered it in dissection of the insertion of the muscles of the tongue to the hyoid bone. The first case reported in American literature was that by Bernays in 1888. In 1922 Hartley collected 44 cases, including one of his own. The condition is found at all ages. In Hickman's case the tumour was of sufficient size to produce suffocation in a new-born child, while Staelin's patient was a woman, aged 77. Although present from the first month of intra-uterine life lingual thyroids seldom produce symptoms before the period of sexual activity, so that they are usually recognised between the ages of 15 and 40. Of the 45 cases now on record, 41 were in females and only four in males. The tumour is usually situated above the hyoid bone in the posterior portion of the tongue at the site of the V-shaped groove. It most frequently occupies a lateral position, though occasionally, as in Bernays's case, it is located centrally surrounding the foramen cæcum. It is usually ovoid in shape, and varies in size from 0·5 to 5 cm. in diameter. The mass usually produces a prominence on the dorsum of the tongue, and when it has reached a certain size projects downwards beneath the mandible and above the hyoid bone. The principal symptom is a feeling of pressure in the throat, causing dysphagia or dyspnœa. A desire to "clear the throat" is usually present for several years before the cause is recognised. Occasionally profuse hæmorrhage occurs from rupture of one or more of the enlarged vessels in the growth. Lingual thyroid must be differentiated from other tumours which occur at the base of the tongue, such as sarcoma, lipoma, angioma, gumma, and lingual tonsil and cyst. Medical treatment in the form of administration of sodium iodide or other drugs has little or no effect. The use of the galvano-cautery should be avoided owing to its inability to remove all the thyroid tissue. Surgical enucleation by the intra- or extra-oral route is the best treatment. The use of X rays is beneficial in cases where removal is impossible or malignant degeneration has taken place. Dr. Tyler's case, which occurred in a man aged 54, was remarkable for the fact that the tumour which had first been noticed eight years previously had undergone malignant degeneration and was complicated by metastases in the lungs. Complete removal was impossible, but X rays and radium caused considerable relief, although the case ended fatally.

THE MODERN CAVE-DWELLER.

THE Henry Saxon Snell Prize, founded by the Royal Sanitary Institute to encourage improvements in the construction or adaptation of sanitary appliances, is to be awarded this year for the best essay on Improvements in the Sanitary Conditions of Underground Dwellings and Small Underground Workshops. The present situation is thus summarised in the circular[2] announcing the conditions of the award.

Throughout London and most large cities, houses of all grades are generally built with basement stories, partly if not wholly below the level of the adjoining street. These basements are used for living quarters and often for offices or workshops. This has been due mainly to the great cost of land, and in a lesser degree to the difficulty of obtaining satisfactory foundations at a comparatively high level. In the old type of house, too, the basement story made it possible to isolate the service and working departments. Economy of ground space was, however, and still is, the ruling factor.

Obviously, without special precautions, these basements cannot compare with the upper floors in the matter of light, cleanliness, and ventilation. A typical London basement is lighted and ventilated from areas at the back and front. These areas vary in width and space according to the grade of the house. Generally there are, beyond the narrow areas in front, vaulted cellars, which may be, and generally are, used for storing coal and coke. Outside in the area are one or more dustbins (from which much dust must escape whenever they are opened for new accretions), and a manhole and fresh-air inlet. The coal, too, may be more or less wet, and the coke will give off sulphurous fumes. The cellars themselves are probably reeking with damp owing to the want of damp-proofing.

Dust from the road will, of course, find its way into all the lower floors of a house, but the basements get the heavier particles, which may be largely composed of horse-droppings, &c. Only too often the area in the rear is in time covered over, and through ventilation ceases. Basement floors are often "solid"—i.e., laid direct on to the ground concrete, and are comparatively colder than the upper floors, even if they are not actually damp.

These are the conditions which have to be faced at the present time. To forbid the use of basements as habitations or workshops might be desirable, but it is not practicable. The Sanitary Institute has been well advised is asking for the coöperation of practical sanitarians in obtaining suggestions as to arrangements that can be made and appliances that can be used for overcoming admitted defects in a really practical way, not prohibitive in cost. It is no use to tell a cave-dweller that he ought to dwell elsewhere when no other dwelling is available for him or his family.

TREATMENT OF LETHARGIC ENCEPHALITIS.

Dr. Hans Hoff [1] gives the following account of the various methods of treatment for lethargic encephalitis employed in the Vienna University Clinic for Psychiatry and Neurology from Jan. 1st, 1916, to May 30th, 1923. Intravenous administration of urotropin as recommended by Economo was employed in 28 cases. The doses consisted of 10 c.cm. of a 10 per cent. solution and ten or more injections were given. The therapeutic effect was almost negative, or at least slight. Economo also made use of iodine in the form of a 50 per cent. solution of sodium iodide or of Pregl's solution,[2] given in doses of 10–150 c.cm. until a total of 1000–1500 c.cm. had been injected. The doses of sodium iodide solution ranged from 4–20 c.cm., a total of 300–400 c.cm. being injected. This method was followed by some improvement, especially in the myoclonic forms, but could not prevent the disease becoming chronic. In forms with meningeal symptoms injection of staphylococci and meningococci caused considerable improvement of these symptoms. Much benefit was also derived in acute cases from a combination of sodium iodide or Pregl's solution with Besredka's typhoid vaccine intravenously, but in chronic cases the results were disappointing. When typhoid vaccine was used by itself considerable improvement took place in the lethargic forms of the disease. In a number of acute cases, vaccineurin—i.e., a combination of the autolysats of *B. prodigiosus* and staphylococcus—was employed with very satisfactory results and appeared to prevent recurrences, but in chronic cases had no effect. In about 25 per cent. of the patients suffering from the chronic sequelæ of encephalitis, including a number of cases of Parkinsonism, inoculation of malaria was of some value, but the improvement was not very considerable. Intravenous injection of sodium cacodylate as recommended by French observers in doses of 0·5 to 2 c.cm. of a 50 per cent. solution appeared to produce some improvement in Parkinsonism and the other sequelæ of encephalitis, but not to any great extent. Dr. Hoff

[2] Pregl's solution: a watery solution containing about 0·04 per cent. free iodine, together with sodium, iodine, hypoiodite, and iodate in ionised form, as defined in the excellent German medical dictionary of Guttman (Medizinische Terminologie. Berlin: Urban and Schwarzenberg. 1923).

concludes that acute encephalitis is amenable to treatment, but that the sequelæ of encephalitis, especially Parkinsonism, have hitherto proved refractory to any form of treatment in most cases.

SEASONABLE ADVICE ON BRONCHITIS.

"IN this cold, damp climate many aged persons contract a fatal bronchitis in bed." These words, from the address on bronchitis delivered by Sir James Barr before the Huddersfield Medical Society on Wednesday last, epitomise the experience of the majority of medical practitioners. The importance of this malady is shown by its position amongst the fatal diseases recorded in the Registrar-General's report, where it ranks above pneumonia, and only just below tuberculosis and cancer. A lecture on such a subject from an authority with years of clinical experience behind him is accordingly of practical interest to us all during the full rigour of the winter. For Sir James Barr emphasises the fact that though the ultimate scientific explanation of the relation of climate to the disease may have changed, yet the importance of atmospheric factors remains as great as ever. The following passage is in his own words:—

"A chill due to exposure is undoubtedly an ætiological factor in the causation of bronchitis, but you must clearly understand what you mean by a chill; a cold, dry, still atmosphere much below the freezing-point cures the bronchial catarrh often associated with tuberculous disease of the lungs. It is a cold wind with a moist atmosphere which chills you to the bone, and finds out the weak spots in your economy. When a person is feverish or well supplied with internal fuel he can stand much external cold. There are on record cases of typhus fever who in their delirium escaped, and after living for some days in the snow without food or clothing recovered. It is quite another matter when the internal temperature is subnormal, and the vital powers depressed from any cause. When the vital resistance is lowered, and especially during sleep when the controlling influence of the nervous system is partially suspended, the individual is much more liable to the catarrhal effects of cold, hence bronchitis is much more frequent and fatal in the very young and very old than in adults."

Sir James Barr is confident that immediate treatment can abort or cut short many cases if dealt with promptly. He says: "When a person after a severe chill has some distress in breathing he should have a warm mustard bath, be put to bed in a warm room, and, if he still feel chilly, have a glass of hot punch. A conscientious teetotaller can have a bowl of hot gruel, but as a rule, teetotallers do not object to punch so long as it is prescribed as a medicine—the only danger is that they may be getting a chill too often. After this he should have no food for 24 hours, but may have plenty of hot water. He can have a Dover's powder, or Sir Archdall Reid's universal panacea of Dover's powder with aspirin and phenacetin. The following morning he should have a saline purge and then remain in bed for two or three days on a starvation diet. By the end of that time he will probably tell you that he is all right, and does not know why you have made such a fuss over a chill. However, when he hears of some of his neighbours dying under similar conditions he will feel more grateful." In a later passage attention is drawn to the importance of the vital as opposed to the merely microbic factor in many of these cases. Speaking of acute suffocative œdema of the lungs, Sir James Barr says: "The pneumococci play a very small part in these cases . . . . the pneumococcus is not such a virulent organism as to kill in a couple of days, even pneumonic plague would scarcely act so rapidly." He assures the practitioner that continuous vigilance on his part is the one road to safety. "By sticking to your patient until you see him past the danger signals you can do far more good than any consultant who comes in, prescribes, gives his opinion and prognosis which may or may not turn out correct, and," adds the speaker drily, "disappears with his fee."

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

LIII.—THE ACUTE MENTAL CASE: ACUTE CONFUSION OR DELIRIUM.[1]

FOR the purpose of this article acute mental cases may be classed in three general groups—viz., acute confusion or delirium, acute depression, and acute excitement. Each of the types may have a rapid or even a sudden onset, and the difficulties of treatment are increased from the outset by the practitioner's frequent and very natural lack of certainty as to diagnosis, prognosis, and duration.

The immediate problem in every case is the decision whether the patient is to be treated at home or removed to a mental hospital. In arriving at this decision, which is often a very important and difficult one, the following considerations must be carefully weighed.

Acute Confusion or Delirium.—The patient's life is, or may at any moment be, in grave danger, and without constant skilled nursing, as well as careful medical treatment, he will very probably die. On the other hand, the duration of the acute illness will probably only be a matter of a few weeks, or often less; the prognosis is excellent if the patient's strength can be maintained; there is nothing in the treatment which the practitioner need hesitate to undertake, given skilled nursing assistance, and there are very understandable objections to applying the present legal machinery of "certification" to a case of acute recoverable illness, which is at least as much bodily as mental.

Acute Depression.—The duration cannot be forecasted, though recovery is a practical certainty. Continual observation and attention will be necessary, various alterations may be required in the accommodation and furnishing of the house, and the patient and his relatives are apt to have a bad effect on each other.

Acute Excitement.—As in depression, the duration is uncertain and the prognosis very good. The patient will need not only observation, but skilled guidance and care, and even with this his state will in all probability cause considerable alarm and distress to those in the house or to near neighbours from time to time.

From this summary it will be seen that the question is largely a financial one. In a reasonably suitable house there is no reason why the treatment of the most acute case should not be undertaken at home, granted the possibility of obtaining ample nursing assistance. Financial and other considerations, however, often combine to make it more convenient to send the patient to a mental hospital. It is always wise to call in, whenever possible, a colleague with special knowledge of psychiatry to share the responsibility of the decision. It will be understood that there are many other types of mental case of more gradual origin and chronic course which may obviously be treated at home without difficulty, or in which there may be other alternatives to home treatment than that of admission to a mental hospital. We are limiting our discussion, however, to acute cases, and what follows is on the assumption that the patient is being treated at home. Only specially important points are referred to, a comprehensive discussion of treatment being impossible in the allotted space.

Acute Confusion or Delirium.

The cases in this group have been variously named and classified as "acute confusion," "acute delirious mania," "the infective exhaustive psychosis," &c.

[1] An article on the home treatment of Acute Depression and Acute Excitement will appear in the next issue of THE LANCET.

The two elements of infection and exhaustion are invariably present, and the more obvious and specific the toxic element is, the more rapidly effective is treatment likely to be. Most acute alcoholic cases are to be included in this class, as also are the cases following childbirth—"puerperal insanity." A typical case recently under care occurred in a naturally nervous and poorly-nourished youth after a minor surgical operation which had gone septic. In considering treatment it is to be remembered that all these cases are essentially similar to those of delirium occurring in, say, enteric fever, or sometimes even in pneumonia. A short prodromal period of semi-stuporose confusion, with vacant appearance, disconnected answers to questions, and fitful attention is common. A patient in such a state may pass into acute delirium at any moment. If not already in bed he must be put there at once, and the services of two thoroughly competent nurses secured without delay. The characteristic signs rapidly make their appearance: great restlessness, rapid pulse and respiration, furred tongue, sordes on lips, large and sluggish pupils, incontinence of urine and fæces, and vivid hallucinations of hearing or sight, with muttering rambling incoherent talk or shouting. Great rise of temperature is not a feature, but a four-hourly chart will rarely, if ever, fail to record some degree of fever. The routine measures are obvious. Quietness, coolness, the absence of glaring light, and abundance of fresh air are essential. Though incontinence is the rule, there is often difficulty in getting the bowels to act in the early stages, and occasionally retention of urine occurs. Finally, careful physical examination must never be omitted. Acute conditions of the appendix, kidney, ovary, and other organs are often overlooked in delirious cases by physicians who have been blinded to the physical possibilities by the prominence of the mental symptoms. Any specific source of toxæmia or local source of infection will be sought for and treated with all energy. In a puerperal case, for example, any abnormal symptoms, such as offensive or suppressed lochia, will be treated as gynæcological and obstetric principles direct. In alcoholic cases, the wisdom of giving small doses of alcohol from the outset has been definitely established. In the absence of any special indications, the treatment is one of a general toxæmia of unknown origin. Blood cultures have been repeatedly made in such cases in the hope of finding some specific organism but with little success. Many of the patients show large numbers of septic sores and pustules which suggest a septicæmic state, and vaccines may be prepared from these and used. Search has long been made for substances which, when injected, will produce a sustained and beneficial leucocytosis in these cases, but whatever may be the theoretical merit of many with which experiment has been made they are rarely of practical help in treatment. Rectal salines are of great use, but it is almost impossible to get the patient to retain them. The constant and exhausting restlessness may sometimes be quietened by tepid sponging, and a cold pack sometimes works like a charm. Frequently, however, the restlessness is so intense and noisy that sedative drugs must be given. This should never be unduly delayed. Such drugs wisely used are a direct means of combating the intense and frequently fatal exhaustion which the sustained restless struggling is doing much to hasten. Paraldehyde is by far the safest and best. It can be given in doses of half an ounce with perfect safety, and repeated ad lib. In a really acute case, however, it may fail to act for more than a very short time, if at all, and recourse must be had to more powerful agents, of which a mixture of morphine (gr. ¼) and hyoscine (gr. 1/75) is probably the best.

Most important of all is the question of food, and it is here that the course of the case lies so largely in the nurse's hands. Not only are the patient's digestive functions more or less in abeyance, but complete refusal of food is a usual characteristic of these cases. Any form of liquid nourishment which the patient can be induced to take is permissible. It should, of course, be given often and in small quantities, and a food chart must be kept on which the amount and nature of the food, and the time of its administration, are noted. The patient is usually far too ill to show any preference for one variety of nourishment rather than another, but may sometimes do so in obedience to hallucinations, or perhaps during a brief lull in his condition. Any such preference should at once be regarded. If the refusal of food is absolute and continued for a day, tube feeding must be resorted to without hesitation. This is an infinitely simpler proceeding than is often imagined, and may be carried out with perfect safety and confidence by any practitioner. The nasal method is easiest and best. The tube should be about the size of a No. 15 catheter, and is joined by a small glass connexion to another rubber tube and glass funnel. The rounded distal end slightly lubricated with oil or glycerine is passed quietly and steadily along the floor of the nose. It will be found that one nostril is almost always very much easier than the other for this purpose. When the tube goes down into the back of the throat it is still moved gently and slowly onwards until a swallowing reflex is evoked and one can feel that it is within the grasp of the pharynx. It can then be pushed boldly onwards. Occasionally, owing to very rapid insertion or undue softness of the tube, it curves forward into the mouth instead of passing into the œsophagus, in which case it must be withdrawn and another more gentle attempt made. The only possible danger is the entrance of the tube into the larynx, and this is so exceedingly rare and produces such obvious signs when it occurs, that it need be no ground for hesitation or alarm. The proceeding is by no means painful, but a delirious patient usually has to be carefully held and controlled while it is carried out. There are many methods of doing this, a simple and effective one being as follows: The patient being on his back, one assistant lies across the bed, his chest coming over the patient's thighs well above his knees. With his hands, which are both free, this assistant holds the hand of the patient which is furthest from him. The second assistant holds the other hand, while a third controls the head, with the aid of a broad towel round the patient's forehead, if necessary. By this means the most violent patient can be controlled with perfect ease, and without possibility of harming him; but in many cases two assistants are amply sufficient. After the tube has been passed, it is wise to introduce first of all a small quantity of water through the funnel to satisfy oneself that the tube has been properly passed into the stomach and that the passage is clear. Milk, custard, and liquid foods of all kinds can be administered in this way, as well as any necessary aperient or hypnotic drug. Sugar and fruit juice are useful additions to a feed. Unfortunately, delirious cases show a remarkable tendency to vomit the food given almost as it enters the stomach. Deftness in introducing the tube and rapidity in withdrawing it will do much to prevent this, but it is a constant and troublesome complication. On more than one occasion during the war, when facilities for dealing with such cases were not good, I had to resort to administering a general anæsthetic after the introduction of the tube, and giving the food and withdrawing the tube while the patient was anæsthetised. This, however, is a last resource, which is not to be recommended. The giving of small quantities greatly lessens the risk of vomiting and a preliminary wash out of the stomach is often of help. As the most intense phase of the delirium passes, the patient can generally be induced to take sufficient food of his own accord. Improvement is rapid, though the confusion tends to come and go in waves before it finally disappears. The further treatment is that of convalescence from acute, exhausting, and dangerous illness.

MEDICINE IN PARLIAMENT.

Death Certification: An Agreed Bill.

The House of Commons, when it is formally opened on Jan. 15th, will include ten medical men among its Members, and if the position of the political parties in Parliament is likely to limit the passing of controversial measures, there is the better opportunity to pass certain non-controversial measures on matters connected with public health.

Law of Death Certification as it Stands.

One such matter, on which legislation is long overdue and which might claim the immediate attention of the Medical Committee, is the certification of death. There seem only two possible elements of controversy: one is the criticism which might be focused upon the suggestion that a number of new officials were being created; the other is the prospect of adding fresh burdens to those which the taxpayer already endures, although money spent on improving our knowledge of the vital statistics of the people may perhaps more properly be regarded as an investment. There is an urgent need for a Bill which will leave no room for the certification of death on insufficient information and which holds out reasonable prospect of eliminating the risk of premature burial or of failure to detect foul play. The present condition of the law is admittedly unsatisfactory. The Select Committee on this subject in 1893 reported that it was possible for evilly-disposed persons to inform a doctor that a patient whom he has been attending has died when such is not the fact, and to obtain a certificate of the cause of death based upon the doctor's previous knowledge of the case. The significance of this was shown in a remarkable trial at Edinburgh six years ago, when two women were charged with thus defrauding insurance companies between the years 1912 and 1917. There were some strong judicial remarks when the judge discovered that the Births and Deaths Registration Act did not prevent a doctor from certifying death without seeing the body. The Departmental Committee on Coroners' Law in 1909 reported that the existing state of the law "offers every opportunity for premature burial and every facility for the concealment of crime." Two Bills, on which we commented at the time,[1] Major L. Molloy's "Coroners' Law and Death Certification (Amendment) Bill" and Dr. A. Salter's "Deaths Registration and Burials Bill," were introduced into Parliament last year, but made no headway. An agreed Bill has now been drafted by a committee convened by the Federation of Medical and Allied Services. It omits Dr. Salter's proposals for "Public Certifiers of Deaths," and it excludes some of the provisions made by Major Molloy for the improvement of the law of coroners. It contains the main safeguards which the two previous Bills were designed to secure; it should not be costly to work, and we recommend it to the support of the medical profession in and out of Parliament.

Provisions of the Agreed Bill.

The chief features of the Bill are these. It proposes that, when a death occurs, information shall be given to the registrar within two days instead of the five-day period at present allowed by the 1874 Act. Every death and every stillbirth is to be registered, but no registration is to take place unless and until the registrar has received a medical certificate first of the fact of death, and secondly of the cause of death. The fact of death is to be certified by a registered medical practitioner who has viewed or examined the body and is satisfied that life is extinct. If possible this will be done by the doctor who last attended the deceased; if this is not possible, the person whose duty it is to notify the death must inform the registrar, and the registrar within 24 hours must inform the coroner, the coroner then appointing a doctor for the purpose. So much for the fact of death. The cause of death is similarly to be certified if possible by the doctor who attended the deceased. If the deceased was unattended, or if the doctor cannot, or does not, give the requisite certificate, the registrar must report the fact to the coroner. These two certificates are to be given on prescribed forms of a distinctive colour, verifiable by means of numbered counterfoils. The practitioner making such a certificate must deliver it within 48 hours to the registrar or to the relative or other person having charge of the remains; in the latter case such relative or other person must himself deliver it to the registrar within 24 hours. Having set up this procedure by which these medical certificates are made indispensable preliminaries to the registration of death, the Bill goes on to provide that human remains are not to be disposed of except upon the authority of a registrar's death certificate or of a coroner's order. The registrar's certificate goes to the "disposal authority"—i.e., the person or body in control or management of the burial-ground, churchyard, cemetery, or authorised crematorium. The person in charge of the register kept at any such burial-ground, &c., must endorse on the certificate a signed statement of the date, place, and mode of disposal of the remains, and must send the certificate back to the registrar within 24 hours. If the registrar does not duly receive it with its endorsement, he is to notify the medical officer of health, who will inquire into the disposal of the body, and will report in writing to the registrar. The Bill provides for duplicating a lost certificate; it also prohibits the retention of human remains in a house in cases not already covered by the Public Health Acts, and it restricts and regulates the disposal of more than one body in a coffin. Of special interest to the medical profession is the proviso (which Major Molloy's Bill had contained) that no practitioner can be required to analyse the contents of a body if he states that he is unable or unwilling to do so. The proposed fee for a medical certificate is half a crown plus a mileage allowance; poor persons' fees will be paid by the guardians or overseers; and there is provision for fees where a doctor acts at the request of a coroner. The machinery thus set up is backed by penalties which are perhaps not very heavy in view of the serious malpractices which the Bill is designed to prevent. The machinery seems adequate to the purpose. If any of our readers can see any dangerous loophole in the proposals, now is the time to draw attention to it.

One other point of importance is the direction that registrars shall furnish gratis to doctors to whom forms are issued a classification of diseases. This standardisation, which doctors are to adopt as far as is practicable in their certificates, will notably improve the statistical information from which important deductions may be expected. The margin of ill-defined deaths has been reduced in recent years, but it is still too large.

Whether or Not to Abolish the Office of Coroner.

In a lecture delivered on Dec. 5th last at the Royal Institute of Public Health by Dr. A. H. Bygott, medical officer of health for West Suffolk, the abolition of coroners was boldly advocated. Dr. Bygott suggested that the medical officers of health of counties and county boroughs should be responsible for determining the cause of death by post-mortem bacteriological chemical examinations or otherwise, and that the legal departments of these local authorities, with the coöperation of the police, should be responsible for holding inquiries in public or in private as to deaths, and for the prosecution of offences in connexion therewith. It is true that the ancient office of the coroner is neither perfect nor indispensable. Critics find it not wholly suited to

[1] The Law of Coroners, The Lancet, 1923, i., 1321.

modern conditions. Scotland has managed to get on very well without it. The only "inquest" known to Scots law is the inquiry as to deaths in prisons: for all other purposes the Fatal Accidents Acts suffice, and the procedure by which the Procurator Fiscal inquires into the cause of sudden or suspicious deaths, the results of such inquiries being transmitted to the Crown Agent in Edinburgh. Nevertheless, we believe that the Bill, which we have outlined above, stands the better chance of becoming an Act of Parliament by avoiding, as it does, any attack upon an ancient institution to which the English public somehow seems attached. The Bill has been drafted by a body representative of all interests concerned. Its proposals are so marked an advance upon the existing law that we should deprecate any alteration of its agreed terms which might jeopardise its career through Parliament.

MEDICAL RESEARCH COUNCIL.

REPORT FOR THE YEAR 1922–23.[1]

THE general plan of the annual reports of the Medical Research Council has now become as familiar as the general policy governing the expenditure of the sum, this year £130,000, annually entrusted to them for disbursement. Approximately a third of this grant-in-aid is allocated to meet the expenses of the National Institute for Medical Research at Hampstead and of the associated field laboratories at Mill Hill, and the rest of the money, apart from a modest provision for expenses, is devoted, as in previous years, to research grants for laboratory and clinical work on specific subjects carried on throughout the country and to the investigations of the Industrial Fatigue Research Board.

The fact that the list of those working under a grant or in honorary association with the activities of the Council contains 593 names and that the bodies or institutions at which correlated work is being carried out are 34 in number is sufficient evidence of the extensive nature of the aid given and of the broad field covered by the sympathetic interest of the Council. On the financial side attention is drawn to certain direct additions made to the material resources of the Council, which have made it possible to undertake a much more ambitious programme than would have been feasible had the Parliamentary grant-in-aid not been thus augmented. Important grants for particular extensions of work have been made by the Carnegie Trust of the United Kingdom (£2000), by the Dental Board of the United Kingdom (£3000), by the Miners' Welfare Fund (£500), and by the Health Committee of the League of Nations (8000 Swiss francs). Grants-in-aid of work jointly undertaken have been made by the Ministry of Health and by the Department of Scientific and Industrial Research. Contributions have been made by industrial associations to the cost of work undertaken by the Industrial Fatigue Research Board appointed by the Council. Various gifts of money have been received from individual benefactors to assist particular schemes of research work. The Council express grateful acknowledgments to the donors of these gifts, which are rightly to be regarded as gifts to the nation for the national enterprise of research. The generous allocation by the Rockefeller Foundation of the sum of $50,000 to be entrusted to the Medical Research Council for the provision of Fellowships [2] in medicine tenable in the United States during a period of three years is noted as one of the most important benefactions of the year.

Changes in the personnel of the Council itself for the year ending Sept. 30th, 1923, have been recorded in our columns as they occurred. The present constitution of the Council and of the committees called together for special investigation is set out below.

[2] THE LANCET, 1923, i., 1323.

The Medical Research Council.

Viscount Goschen (Chairman), Lord Mildmay of Flete, P.C. (Treasurer), Mr. William Graham, M.P., Sir Frederick Andrewes, M.D., F.R.S., Prof. Georges Dreyer, M.D., F.R.S., Prof. T. R. Elliott, M.D., F.R.S., Sir Archibald E. Garrod, M.D., F.R.S., Dr. Henry Head, F.R.S., Prof. D. Noël Paton, M.D., F.R.S., Sir Cuthbert S. Wallace, F.R.C.S., Sir Walter M. Fletcher, M.D., F.R.S. (Secretary).

Investigation Committees for Special Subjects.

Biological Standards and the Methods of Biological Assay.—Prof. William Bulloch (chairman), Sir Frederick Andrewes, Dr. H. H. Dale, Prof. Georges Dreyer, Sir Walter Fletcher, Prof. C. J. Martin.

Bacteriology (formerly Pathological Methods).—Sir Frederick Andrewes (chairman), Prof. Bulloch, Captain S. R. Douglas (secretary), Prof. Dreyer, Dr. Paul Fildes, Prof. J. C. G. Ledingham, Dr. C. G. L. Wolf.

Anthropometric Methods and Standards.—Sir Arthur Keith (chairman), Lieut.-Colonel C. R. Sylvester-Bradeley, R.A.M.C., Dr. John Brownlee, Prof. Dreyer, Group-Captain Martin Flack, R.A.F., Dr. F. G. Hobson (secretary).

Ante-Natal and Post-Natal Problems of Child Life.—London Committee: Dr. G. F. Still (chairman), Dr. John Brownlee, Dr. Hector C. Cameron, Dr. J. S. Fairbairn, Dr. Eardley L. Holland, Dr. R. C. Jewesbury, Prof. M. S. Pembrey, Dr. O. L. V. de Wesselow (secretary). Scottish Committee: Prof. D. Noël Paton (chairman), Dr. A. K. Chalmers, Dr. Leonard Findlay, Dr. T. Y. Finlay, Dr. G. B. Fleming, Prof. J. M. Munro Kerr, Sir Leslie Mackenzie, Prof. B. P. Watson, Miss Jean Agnew (secretary).

Eclampsia (jointly with the Obstetrical and Gynæcological Section of the Royal Society of Medicine).—Dr. T. W. Eden (chairman), Mr. A. W. Bourne, Dr. Eardley L. Holland, Prof. Louise McIlroy, Dr. A. J. McNair, Dr. Everard Williams, Dr. Herbert Williamson (secretary).

Accessory Food Factors ("*Vitamins*") (appointed jointly with the Lister Institute of Preventive Medicine).—Prof. F. Gowland Hopkins (chairman), Miss Harriette Chick, D.Sc. (secretary), Mr. J. C. Drummond, D.Sc., Prof. Arthur Harden, Mr. W. B. Hardy, Dr. A. W. J. MacFadden, Prof. C. J. Martin, Prof. Edward Mellanby.

Quantitative Problems of Human Nutrition.—Prof. E. P. Cathcart (chairman), Dr. Major Greenwood (secretary), Dr. Leonard Hill, Dr. A. W. J. MacFadden, Sir Thomas Middleton, Prof. D. Noël Paton, Prof. T. B. Wood.

Causes of Dental Disease.—Prof. W. D. Halliburton (chairman), Dr. Norman G. Bennett, Dr. Leonard Colebrook, Mr. W. H. Dolamore, Dr. J. M. Hamill (secretary), Sir Arthur Keith, Mr. P. P. Laidlaw, Mrs. M. Mellanby, Dr. J. Howard Mummery, Dr. C. J. Thomas.

Clinical Uses of Oxygen.—Prof. T. R. Elliott (chairman), Prof. F. R. Fraser, Dr. G. H. Hunt (secretary), Prof. J. C. Meakins, Dr. E. P. Poulton.

Injuries of the Nervous System.—Dr. E. Farquhar Buzzard (chairman), Mr. W. Rowley Bristow, Dr. J. G. Greenfield, Dr. Henry Head, Dr. George Riddoch (secretary), Mr. Percy Sargent, Mr. Wilfred Trotter.

Mental Disorders.—Dr. Henry Head (chairman), Dr. Thomas Beaton (secretary), Dr. C. H. Bond, Dr. Henry Devine, Prof. G. Elliot-Smith, Sir Frederick Mott.

Tuberculosis (Subcommittee at present organised under a Committee of the Council, of which Dr. A. S. MacNalty is th Secretary).

Tuberculin.—Capt. S. R. Douglas, late I.M.S. (chairman), Mr. W. Buckley, Dr. L. S. T. Burrell, Prof. J. B. Buxton, F.R.C.V.S., Prof. Dreyer, Mr. J. Macintosh, Dr. MacNalty, Dr. H. H. Thomson, Dr. P. C. Varrier-Jones, Dr. G. T. Western, Prof. T. B. Wood.

Bacteriology of Tuberculosis.—Prof. Dreyer (chairman), Dr. R. G. Canti, Prof. S. L. Cummins, Dr. A. Stanley Griffith, Dr. A. C. Inman, Dr. MacNalty (secretary).

Salvarsan.—Sir Humphry Rolleston (chairman), Sir Frederick Andrewes, Prof. William Bulloch, Dr. F. J. H. Coutts (secretary), Dr. H. H. Dale, Dr. L. W. Harrison, Dr. J. W. McNee.

Canine Distemper.—Prof. C. J. Martin (chairman), Prof. J. B. Buxton, F.R.C.V.S., Capt. S. R. Douglas, Prof. F. Hobday, F.R.C.V.S., Mr. A. L. Thomson, D.Sc. (secretary).

Radiology.—Sir Cuthbert Wallace (chairman), Dr. C. Thurstan Holland, Dr. E. H. Kettle, Dr. Robert Knox, Sir Humphry Rolleston, Prof. Sidney Russ (secretary), Prof. S. G. Shattock.

Biological Actions of Light.—Sir William Bayliss (chairman), Mr. J. E. Barnard, Dr. H. H. Dale, Capt. S. R. Douglas, Prof. Dreyer, Sir Henry Gauvain, Dr. Leonard Hill, Dr. J. Henry Sequeira, Mr. Edgar Schuster, D.Sc. (secretary).

Cinchona Derivatives and Malaria.—Dr. H. H. Dale (chairman), Major H. W. Acton, I.M.S., Dr. Andrew Balfour, Lieut.-Colonel S. P. James, late I.M.S.

Properties of Hæmoglobin.—Mr. Joseph Barcroft (chairman), Sir William Bayliss, Dr. H. H. Dale, Dr. C. G. Douglas, Prof. C. A. Lovatt Evans, Mr. W. B. Hardy, Dr. H. Hartridge, Prof. Laurence J. Henderson (Harvard), Prof. A. V. Hill, Dr. J. H. Burn (secretary).

Physiological Actions of Alcohol.—Prof. A. R. Cushny, Dr. H. H. Dale, Dr. Major Greenwood, Sir Frederick Mott, Dr. C. S. Myers, Sir Charles Sherrington, Dr. W. C. Sullivan.

Use of Pituitary Extract in Labour (jointly with the Obstetrical and Gynæcological Section of the Royal Society of Medicine).—Dr. H. Russell Andrews (chairman), Mr. A. W. Bourne, Dr. H. H. Dale, Dr. Malcolm Donaldson (secretary), Dr. J. P. Hedley, Prof. Louise McIlroy.

"Status Lymphaticus" and Causes of Unexplained Death (jointly with the Pathological Society of Great Britain and Ireland).—Dr. G. M. Duncan, Prof. J. Shaw Dunn, Prof. F. Emrys-Roberts (secretary), Prof. E. E. Glynn, Dr. J. E.

McCartney, Prof. Matthew J. Stewart, Prof. H. M. Turnbull, Prof. G. Haswell Wilson.

Miners' Nystagmus.—Dr. J. S. Haldane (chairman), Prof. E. L. Collis, Dr. T. L. Llewellyn (secretary), Mr. G. H. Pooley.

The Industrial Fatigue Research Board and the Related Scientific Committees.—The Board: Mr. William Graham, LL.B., M.P. (chairman), Mr. R. R. Bannatyne, Mr. C. J. Bond, Mr. W. L. Hichens, Dr. C. S. Myers, Sir Joseph Petavel, Sir Charles Sherrington, Prof. E. H. Starling, Miss Mona Wilson, J.P., Mr. D. R. Wilson, M.A. (H.M. Inspector of Factories) (secretary).

Industrial Health Statistics.—Dr. Major Greenwood (chairman), Dr. John Brownlee, Prof. E. L. Collis, Mr. Alfred Henry, F.I.A., Dr. Leonard Hill, Mr. L. Isserlis, Dr. A. S. MacNalty, Mr. G. Udny Yule, Mr. T. Lewis-Faning (secretary).

Physiology of Muscular Work.—Prof. E. H. Starling (chairman), Prof. E. P. Cathcart, Prof. A. V. Hill, Prof. M. S. Pembrey, Dr. B. A. McSwiney (secretary).

Industrial Psychology.—Dr. Henry Head (chairman), Mr. F. C. Bartlett, M.A., Mr. Cyril Burt, M.A., Dr. C. S. Myers, Prof. T. H. Pear, Sir Charles Sherrington.

Legibility of Type.—Sir John Parsons (chairman), Mr. F. C. Bartlett, M.A., Dr. H. Hartridge, Mr. L. A. Legros, M.I.C.E., Mr. E. Schuster, D.Sc. (secretary).

Two Groups of Inquiries.

In the introduction to the report which is signed by Lord Goschen as chairman and Sir Walter Fletcher, F.R.S., as secretary, it is pointed out that the work of which the Council now presents an account will be found in the main to fall within two groups, not sharply distinct. On one hand there are studies which will seem to all readers to have obvious importance as pieces of medical research directly applied to the better maintenance of health or the better treatment of disease. Their urgency and value are at once obvious. On the other hand, there is no less important work of which the nature and purpose cannot so easily be appreciated, and the bearing which it has upon the improvement either of medicine or hygiene may seem more remote.

The Council finds it easy enough to get general approval for direct experimental study of particular diseases in the hope of gaining means of cure or prevention. All, again, can see the importance of finding the best physiological conditions for bodily labour of different kinds, or of studying the actions of light upon the body and the interplay of sunshine and nutritive factors in healthy growth.

It is in the latter group of studies, including perhaps the greater part of the work which the Council are supporting, that the chief difficulties of justification within short compass are found. It is not easy to explain, except at great length, the relations which studies of this kind have to the problems of practical medicine. Work upon detached points in biochemistry investigations of the laws of bacterial growth under given conditions, studies of cell life and organisation, inquiries into the behaviour of colloidal substances, all these seem often not only to the lay public but even to the practising doctor to be far divorced from useful human purposes. Neither the volume nor the value of the highly elaborate, patient, and unadvertised work which is being done in these apparently academic directions is generally realised. It goes forward, filling gaps in knowledge and forging new weapons for further work by finding new methods or instruments of research. Abundant experience is available to show that at any moment some piece of knowledge or some new laboratory method emerging from research work of this kind may bring altogether unexpected aid to the solution of some practical problem and so, whether early or late, find its fruition.

Their Inter-relations.

Effective illustration of the relations between these two intermingling groups of work is drawn from what the report describes as perhaps the most conspicuous medical event of the past year—the introduction to practical therapeutics of insulin. It is emphasised—not in order to belittle the Canadian workers, but to give their excellent work its due credit as a scientific and not a chance discovery—that this sort of "discovery" is the end-point of a long series of scientific steps each of which was as truly a "discovery" and each of which was accomplished by men exceptionally gifted. Some at least of these efforts made on these lines in the past were probably abortive for want of parallel progress in the technical methods available for rapid estimation of small quantities of sugar in the blood. The brilliant result of a bravely renewed attack upon a problem which many of their predecessors had abandoned as almost hopeless by Dr. F. G. Banting, Mr. C. H. Best, Prof. J. R. R. MacLeod, and Dr. J. B. Collip, of Toronto University, is now a matter of world history. We rejoice that the report mentions Dr. Collip's name in this connexion, for it is apt to be forgotten that while Banting put out of action the trypsin secreted by the main pancreatic glands by a preliminary ligature of the ducts, it was Collip who devised a means of achieving a similar result on a large scale by the use of alcohol.

The Application of Funds to Promote Medical Progress.

The Council notes that there are signs in some directions of a growing tendency to yield to the temptation to give or to ask money not for the steady cultivation of knowledge along the natural lines of growth, but for the attempted purchase of practical fruitfulness before its time. Stimulated by notable and obvious achievements like the production of diphtheria antitoxin, preventive inoculation against typhoid, the defence against scurvy and rickets through dietetic knowledge, the control of body function by pituitary extract or by insulin, the public, and indeed some parts of the medical profession, are tempted to think that money collected directly for the discovery of similar practical boons, or that rewards offered to particular discoverers, will aid progress, instead of learning the lesson of experience and seeking the due provision of money for disinterested scientific work and the due support of the ablest scientific men to do it. As the Council said in its annual report four years ago, and now repeats, power to prevent or cure a disease must not be expected to come by sudden discovery, nor often as the result of a special campaign, however vigorously prosecuted. Rapid gains, often unforeseen and in unexpected directions, may be confidently expected, however, so long as the area of accurate knowledge is maintained in its growth; we cannot foretell the flow of water here and there in the irrigating channels along a shore, but we know that the flow must certainly follow whenever the tide raises the general level of the waters.

Animal Experiments.

The Council draws attention from another point of view to the production and successful use of insulin in the treatment of diabetes. The functions of the pancreas in the control of diabetes were first elucidated by the study of diabetes artificially inflicted upon dogs. At every subsequent stage in progress animal experiment has been necessary, and even now every batch of insulin must be tested upon animals for the assessment of its potency. The great service rendered by animals to mankind, of which this is only one example, must be counted as a higher service than that which is given by animals to provide the clothing, the food, or the amusements of mankind. It is plainly right that this high service should be gratefully recognised and openly acknowledged by the whole community that takes advantage of it. In their last annual report the Council referred at some length to their hopes for a better organisation in this country of the study of animal diseases, which, quite apart from the benefits to be expected from it for agriculture, and, through the veterinary profession, for the benefit of all domesticated animals, must bring invaluable help to medicine. The veterinary and medical sciences are not different sciences, but occupy the same field of pathology, which both in theory and practice must always be a comparative pathology. On this account the Council cordially welcome the establishment of a chair and a school of animal pathology in the University of Cambridge.

The National Institute of Medical Research.

The 17 pages devoted to admirably condensed summaries of the type of investigations being undertaken in the six departments of the Institute are well worth careful study. It has fallen to the Department

of Biochemistry and Pharmacology, under the direction of Dr. H. H. Dale, F.R.S., to undertake the arduous task of organising the preliminary trials, methods of preparation and standardisation of insulin, and Dr. H. W. Dudley is now engaged in investigating its chemistry. Dr. J. H. Burn has observed an interesting antagonism between extracts of the posterior lobe of the pituitary body and insulin in their effects on the blood-sugar. It is interesting to learn that the conclusions reached by Dr. Dale and Dr. H. King, working in association with Dr. C. F. Hadfield, on the anæsthetic action of pure ether (THE LANCET, March 3rd, 1923) have been completely confirmed by the concurrent and independent observations of Prof. Storm van Leeuwen and his colleagues at the University of Leiden, who find that ether purified by crystallisation with organic substances retains its full anæsthetic potency. In the Department of Experimental Pathology, Bacteriology, and Protistology, Captain S. R. Douglas, F.R.S., the director, has undertaken experimental work on the nature and actions of diaplyte vaccine, introduced by Prof. G. Dreyer, and during the early part of the year continued his investigations into rat leprosy, this work having been more recently undertaken by Dr. P. P. Laidlaw, with encouraging results. Dr. W. E. Gye has developed his work with Dr. W. J. Purdy on the action of colloidal silica administered to animals, and is now devoting most of his time to the study of filter-passing organisms, and has cultivated such an organism from chicken sarcomas. Dr. Laidlaw has studied the nutrient factors which stimulate the growth of bacteria, Dr. Percival Hartley has been mainly occupied in the preparation of a standard diphtheria antitoxin, while Mr. Clifford Dobell, F.R.S., has continued his work on the improvement of technical methods for the investigation of very minute organisms, and his studies of the amœba, coccidia, and spirochætes which infect man. In the Department of Applied Physiology, Dr. Leonard Hill, F.R.S., the director, Dr. J. Argyll Campbell, and other workers have continued their studies of the chemical exchanges of the body and their efficiency, undertaken with special reference to open-air treatment of disease and to the hygiene of physical labour. Dr. Major Greenwood (Ministry of Health) has received accommodation in the Institute for statistical inquiries, and has coöperated with the staff in various ways. The Council records its continued indebtedness to Mr. J. E. Barnard for his honorary services as director of the Department of Applied Optics. For better study of the biological actions of light a photometric method of measuring the relative energies of ultra-violet radiations has been adopted. A brief note of the work of the Statistical Department (Dr. John Brownlee, director, and Dr. Matthew Young), and of the Library and Publications Department concludes this section of the report.

Biological Standards: Research Work in Clinical Units.

The third section of the report is devoted to the determination of biological standards and the methods of biological assay and measurement. This includes a description of the work done upon biological standards at the National Institute for Medical Research, an account of the national collection of type cultures, the production of standard diagnostic sera and cultures, a discussion of international serological standards, and of anthropometric methods and standards of medical measurement. The Council's Department of Clinical Research is housed at University College Hospital, London, under the direction of Sir Thomas Lewis, F.R.S., and a long list of publications testify to the excellent original work being carried out by the director, Dr. A. N. Drury, Dr. R. T. Grant, Dr. C. C. Iliescu, and the large number of voluntary workers from all parts of the world who have considered it a privilege to work in the department. These include Dr. T. F. Cotton, Dr. A. Sebastiani (of Rome), Dr. W. Horsfall (of Sydney), Dr. C. W. Munley (of Portland, Oregon), Dr. H. L. Blumgart (of Boston), Dr. J. J. Sumbal (of Bratislava), and Dr. F. Smith (of Chicago). The research work being done under grants from the Council at various other London, provincial, and Scottish hospitals is also indicated. Mostly this work is again referred to in more detail in the next section of the report entitled

Research in Specific Subjects.

We shall have to return on innumerable occasions to the consideration of the mass of work described as in progress throughout the country. It must suffice here to give a list of the headings into which it is classified and to recommend this section of the report for special study. The headings include: Problems of Child Life—Rickets, Accessory Food Factors ("Vitamins")—Studies of Deficiency Diseases in Central Europe, Human Nutrition, Dental Disease, Disorders of the Cardio-vascular System, Exophthalmic Goitre (Graves's Disease), Disorders of the Respiratory System, Disorders of the Excretory System, Disorders of the Nervous System, Mental Disorders, Tuberculosis, Studies of the Streptococcus and Pneumococcus Group, Diphtheria, Venereal Diseases, Filtrable Viruses—Canine Distemper, Diabetes and Insulin Treatment, Arthritis, Malignant Disease, Radiology and Radiotherapy, the Biochemical Actions of Light, General Biochemical Researches, General Physiological and Pathological Researches, Experimental Epidemiology, Metazoan Parasitology.

Conclusion.

After a section devoted to industrial medicine and industrial fatigue a concluding paragraph of the report pays a special tribute to the invaluable aid given to the Council's work by the numerous scientific men who have been willing to give their time to serving on committees in charge of particular investigations. The list of investigation committees set out above is the clearest proof that there are few subjects of topical and urgent medical interest which are not receiving the earnest attention of the Medical Research Council. It is not possible to do justice in any summary of so pithy and condensed a report as this one. We can only hope to indicate its scope.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

The New Medical Bill.

THE representatives of the medical profession have now been informed of the leading principles underlying the proposed Medical Act which the Government is about to lay before the National Assembly. That the Medical Council was not even invited to coöperate in drafting the principal clauses of this Bill was considered, at the time, as an insult to the profession, and now it is anticipated that the contents of the Bill will cause even wider dissatisfaction among doctors. The promises made to the profession within the last three years would appear to have been forgotten, and the desire to control the rights and duties of doctors by non-medical men is manifest. Thus, for instance, a disciplinary court consisting of four doctors and five lawyers or officials is entrusted with the control of professional infringements of law, but of these four medical men two are to be chosen from State officers of health. This court would have power to strike the name of a culprit off the Medical Register for a period of one to six years. All minor offences would go before the Medical Council, but all serious cases would be judged by this largely non-medical court. A chapter deals with professional secrecy. Under the new Act the doctor would be bound to disclose to the judge in a court of law any details about his patients that might be demanded, and important "personal or public interests" would justify a breach of professional secrecy! At present a doctor is not bound to take over the treatment of a patient except in case of urgent need—in this Bill

no doctor may refuse professional help unless absolutely unable to do so. As regards the medical curriculum, the old desideratum of the profession—viz., that a compulsory "hospital year" be added to the normal five and a half years' course of training of the medical student will not be realised, but a clause states, that in certain conditions this additional year might be stipulated "if found advisable." In a word, the Bill violates the all-important principle that affairs pertaining to the welfare of a certain profession be controlled by members of that particular profession only. It is not to be wondered at that the articles and clauses as stipulated in the suggested Act are far from finding the approval of those most concerned. A strenuous fight against such bureaucratic methods is natural, and the profession is once more firmly united in the struggle for self-determination.

Experimental Principles in the Treatment of Cardiac Insufficiency.

At a recent meeting of the Vienna Biological Society Prof. Wiechowsky read an interesting paper on the above subject, in which he stated that the modern researcher decides the possible remedial efficacy of various substances from the analysis of their experimental effects on the organs. Information thus obtained is more reliable than the knowledge gained by general experience and bedside indications alone, but laboratory findings must be controlled by clinical observations. He reported chiefly on the results of his experiments conducted solely on the frog's heart with a view to ascertaining the correct use of cardiac analeptics. The hearts were completely anæsthetised with chloroform and other toxic drugs, and the substances used as analeptics were: caffeine, adrenalin, digitalis, camphor, calcium salts, and physostigmine. He finds that caffeine can be used universally as an analeptic for all conditions of cardiac insufficiency. The derivatives of digitalis are useful only where failure of compensation through organic valvular disease has taken place. Camphor increases the minute-volume of blood only in cases of fibrillation (extra-systole). Its action in this respect is identical with that of strychnine or quinine, and has an equally weakening effect on the muscular action. Therefore it should be combined with caffeine or digitalis. Adrenalin throws extra work on the cardiac muscles by increasing the pressure. Therefore it should not be used alone in cardiac insufficiency; its chief indication is collapse due to paralysis of the central vaso-motor centres, the heart being otherwise intact. The cardiac analeptics should be injected intracardially in all instances of severe insufficiency or even in cases of complete standstill of the heart. Even after a few minutes of absolute cessation, heart-beats may be recommenced by this procedure. Before starting a chloroform narcosis, caffeine or theobromine should be injected subcutaneously so as to prevent a syncope.

Justification of Artificial Abortion: A Medical Protest against Present Jurisdiction.

In my letter of Dec. 15th, 1923, I called attention to the alarming increase of criminal abortion in Austria as instanced by Prof. Latzko, and referred to a growing body of opinion which was endeavouring to legalise artificial abortion before the third month of pregnancy. The law, however, maintains a very uncompromising attitude of unremitting severity towards any such procedure. Several months ago, as I mentioned in a previous letter (THE LANCET, June 23rd, 1923) the Supreme Public Prosecutor issued an order to all medical corporations, boards of health, and hospitals, demanding that in every instance of abortion where an external cause might be suspected, a report should be made to the police by the doctor or midwife. This attempt to tamper with professional secrecy was absolutely repudiated by the profession, and it may be stated that neither in hospitals nor in private practice were any questions asked which might have caused trouble to the woman. But quite recently the High Court took opportunity to commit two eminent members of the Vienna medical world for trial because the one had advised the inducement of an artificial abortion, and the other had operated on the woman in question. Both were sentenced to three months' imprisonment on the testimony of the forensic expert, who stated that from the data obtained from the patient after several months and from the notes of the case-history in the private cottage hospital, he had come to the conclusion that the abortion was not a matter of necessity. The point is that while both men were fully qualified practitioners of some standing, the expert was a forensic pathologist, and as such no clinician. The incident caused a violent outburst of indignation in the profession; in mass meetings and in the press the present rôle of the forensic expert was severely criticised. In a resolution passed by the Medical Council and the meetings of the Specialists' Union, the Government was informed, in particular the Ministry of Justice, that the profession refused to be subjected to antiquated methods of jurisdiction. Medicine had made such enormous strides in the last 30 years that it was absolutely necessary to obtain the opinion of the clinician who was abreast with modern practical medicine, whenever medical problems were concerned. The pathologist, on the other hand, however high might be his standing in his own branch, lacked the experience obtainable only at the bedside of the patient. In judging the pros and cons of a case of abortion the Medical Council thought it "of paramount importance that a clinical expert be called upon to advise the judge and the court." This resolution also found a most hearty support in the public lay press. The reactionary turn taken lately by the bureaucracy and jurisdiction in this country is being much resented and commented upon by all sections of the community.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

THE following Surg. Comdrs. are placed on the ret. list with the rank of Surg. Capt.: S. Roach, J. Stoddart, R. S. Osborne, H. P. Turnbull, A. Woollcombe, and K. H. Jones.

Surg. Capt. R. A. Ross is placed on the ret. list with the rank of Surg. Rear-Admiral.

W. G. C. Fitzpatrick to be Surg. Lt.

ROYAL ARMY MEDICAL CORPS.

Temp. Capt. T. Bourne-Price relinquishes his commn. and retains the rank of Capt.

REGULAR RESERVE OF OFFICERS.

Lt.-Col. J. F. W. Sandison, late R.A.M.C., Militia, to be Lt.-Col.

TERRITORIAL ARMY.

Sanitary Companies.—Capt. J. Ogilvie resigns his commn. and retains the rank of Capt.

Supernumerary for Service with the O.T.C.—Maj. (Prov.) C. H. Carlton, from General List, to be Maj. (Prov.) for service with the London University Contingent, O.T.C.

TERRITORIAL DECORATIONS.

The King has conferred the Territorial Decoration upon the undermentioned officers: Lt.-Cols. T. A. Barron, D. J. Graham, J. M. Gover, W. Lister, G. S. A. Ranking (ret.), and D. G. Rice-Oxley; Majs. A. C. Goodwin, D. V. Haig, A. Ayre-Smith, and G. E. J. A. Robinson; and Capt. (Bt.-Maj.) C. W. Wirgman (ret.).

ANTI-OPIUM PROPAGANDA IN CHINA.—Dr. Chuan, formerly director of the Chinese Army Medical College for six years, has been appointed secretary of the Opium Committee of the National Christian Council of China, which has now moved from Shanghai to Peking, so as to be able the more effectively to work with Dr. W. H. G. Aspland, of the International Anti-Opium Association. Dr. Chuan graduated at Peiyang Medical College and afterwards studied at Johns Hopkins and Harvard. For a short time in 1922 he was Vice-Minister for Education, and last year he became director of the Central Sanitary Department, Peking. He expects to be chiefly engaged in providing anti-opium literature in Chinese, particularly for the Chinese Church.

THE CAPITATION FEE FOR INSURANCE PRACTICE.

THE OPENING SESSIONS OF THE COURT OF INQUIRY.

THE Court of Inquiry appointed by the Minister of Health to determine what should be the amount of capitation fee payable to insurance practitioners held its first sitting on Friday, Jan. 4th, at the Ministry of Health. The chairman of the Court is Mr. T. R. Hughes, K.C., the other two members being Mr. F. C. Goodenough and Sir Gilbert Garnsey, K.B.E. The minute of appointment directs the Court

"to enquire and report to His Majesty's Government what should be the amount of the capitation fee (per insured person per annum) on the basis of which the Central Practitioners Fund under Article 19 of the National Health Insurance (Medical Benefit) Regulations, 1924, should be calculated as from the 1st January, 1924, so as to afford adequate remuneration for the time and service to be given by general practitioners under the conditions set out in those Regulations, in connection with the medical attendance and treatment of insured persons, due regard being had to the service in fact rendered under the Regulations hitherto in force. This capitation fee is not to include any payment in respect of the supply of drugs and appliances (such payments being made out of the Drug Fund under Article 24 of the Regulations), nor any payments to meet the special conditions of practice in rural and semi-rural areas."

FRIDAY, JAN. 4TH.

In opening the proceedings the Chairman said the Court had before them the printed case submitted by the Insurance Acts Committee of the British Medical Association; the printed case of the Ministry of Health and the Secretary for Scotland; and a memorandum by the Medical Practitioners' Union. The Emergency Committee of the Approved Societies' Association had now decided to submit their views to the Court.

The Attitude of the Approved Societies.

Dr. Alfred Cox, medical secretary to the British Medical Association, entered a protest against the action of the approved societies who, after having stated that they did not intend to take part in the proceedings, had now, after the evidence of his association and of the other parties had been put in, changed their minds. It appeared that their action would delay the proceedings and postpone the report of the Court. The societies were "trying to make the best of both worlds"; he hoped they would come before the Court, but they should do so on the same terms as the other parties.

Mr. Scott, assistant secretary to the Emergency Committee of the Approved Societies' Association, stated that he was present with a watching brief to listen to the proceedings on behalf of the Emergency Committee. The approved societies proposed to give evidence at the request of the Ministry, but they had no desire to be represented at the inquiry that day. Their case would not be ready before the 20th.

The Chairman said that there seemed to be a misapprehension. The Ministry had not requested the societies to give evidence, but had intimated that they would be glad if the societies thought it desirable to do so. The representatives of approved societies should understand that they were at liberty to take part in the inquiry, but the inquiry could not be delayed until their case was put in. He hoped that the societies would prepare their case before the 20th.

Dr. Cox drew attention to the fact that Mr. Percy Rockliff, secretary of the Joint Committee of Approved Societies, was reported that morning in the press to have given as a reason for the decision of the societies to take part in the proceedings, the changed personnel of the Court. Apparently they did not think the Court was impartial until Sir Josiah Stamp was dropped out. His Association believed that the Minister of the Crown would not appoint a Court which was not impartial, and he felt it was due to the decencies of public life that a protest should be made.

The Chairman said that the matter mainly affected the Tribunal, which would be quite indifferent to it.

The Case for the Doctors.

Dr. H. B. Brackenbury, chairman of the Insurance Acts Committee of the British Medical Association, then gave evidence in amplification of the Association's printed case. He said that they were there in no partisan spirit; they desired to do all that they could to assist the Court of Inquiry. There were certain important points of principle which he would like to emphasise at the outset. (1) The medical profession as such was deserving of relatively high remuneration; all those indications which would justify a relatively high rate of pay were to be found in the medical profession. (2) Insurance doctors should, so far as possible, be placed on the same footing, financially, as the rest of the profession, otherwise the best men would be drawn to other branches of professional work. (3) The capitation fee was uniform throughout the whole service; therefore regard must be had to the higher as well as to the lower conditions prevailing in that service. (4) It was necessary that such a rate of payment should be given as would not only attract but also retain the services of first-class doctors.

The conditions of medical practice were to-day very different from those existing 10 or 12 years ago. Doctors had now to devote a great deal more time in investigating cases of illness. The general practitioner treatment of to-day to which the insured person is entitled was something larger than was in their minds when the National Insurance Act first came into operation. The doctors had themselves on several occasions suggested the enlargement and extension of the service, and it was the desire of the medical profession that a very complete general practitioner service should be available for the insured population. They must, however, have regard to the increase in the doctor's work consequent on the advance of medical science on the one hand and on the extended scope of general practitioner treatment on the other.

As regards the statistical side of their case, the figures had been prepared by Prof. Bowley, who had explored the subject as an independent statistician. The figures had been in no way modified by the Association. The conclusion drawn from these figures was as follows: Assuming that they applied all the economic principles which had been learned since the war and that they accepted the same relative standard of conduct, they would require, in order to maintain the 1913 standard of living, a capitation fee of something over 11*s.* as compared with the 7*s.* 3*d.* of 1913, and even then the relative saving capacity of the doctor would be reduced from £100 to £42—an amount barely sufficient to cover insurance premiums.

The Ministry had suggested a comparison with the fluctuations in the bonus paid to civil servants, but in their opinion this was not a satisfactory way of apprising relative values. It was a doubly doubtful analogy, for the alterations in the Civil Service bonus was in itself a doubtful method of deciding relative values, and to apply this doubtful test to the materially different conditions of the medical profession rendered the result still more doubtful. The Ministry had applied the Civil Service bonus figures to the maximum instead of to the average of the doctor's remuneration. Moreover, at no time had the increase in the insurance doctor's remuneration been adjusted to anything like the height of the Civil Service bonus. Apart from his pay, the civil servant received pension, holiday, and other advantages which had no counterpart in the doctor's practice. The only true analogy would be obtained if the value of these special benefits were deducted before the bonus curve were planned, their value being subsequently added to the resultant figure for the doctor's remuneration. With reference to the cost of carrying on a practice, it was clear that a reduction in cost of materials did not carry with it a

reduction of practice expenses in the same proportion. Considering only non-dispensing practices, he considered that the average practice expenses were about 25 per cent. of gross income.

There were certain validity tests which could be applied to the capitation fee for which they asked. The first was the standard of fees paid to a doctor in his private practice. Omitting the exceptional practices where the patients had very small means, the private fees normally received for similar services were fairly comparable with the capitation fee of from 10*s.* 4*d.* to 10*s.* 9*d.*, which they claimed. It must be remembered that in private practice a doctor receives extra payment for many services—e.g., night visits, operations, administration of anæsthetics, which are included in his insurance contract. Another test was the contract service outside the National Insurance Acts. In this class of work there was almost invariably a restricted service, with extra fees for special services, and frequently members were accepted only after medical examination; yet they found that, with few exceptions, the club doctors received a higher capitation fee than the insurance doctor.

There was the further suggested test of the "Time Rate Equivalent." In his opinion they were, on this matter, still groping after the full facts; he thought that both the Ministry and the profession had been wrong in the time equivalence tests which they had sought to apply in 1920. It seemed to him impossible to apply the time factor to the profession. The doctor's work involved constant application and absorption. He had to apply the whole of his professional knowledge to what he did. They strongly objected to the suggestion that it could be said that certain services required only a certain number of hours out of the 24, and that the payment should be based on such calculations. In the interests of national health it was necessary to allow a measure of spare time; if all doctors were kept fully employed for periods of normal illness there would be no reserve to meet times of epidemic. The Ministry suggested that only one-half of a doctor's time would be occupied in looking after 2000 patients. This involved the conclusion that 8000 doctors fully occupied would be sufficient to carry on the whole general practice of the country. In fact, the number of doctors was two and a half to three times in excess of that figure, and it was absurd to suggest that they were all surplus to requirements.

In conclusion, Dr. Brackenbury said that the amount which the capitation fee would bring to the individual doctor must represent the translation into terms of income of all the services which the doctor was required to render under his agreement with the Insurance Committee. In deciding that amount it was necessary to have regard to the present cost of living, to the extensive character of the services which were involved, and to the need for maintaining a high standard of professional efficiency in the National Insurance Service.

In reply to questions addressed by members of the Court, Dr. Brackenbury stated that the average private fees might be taken as 3*s.* 6*d.* for a consultation and 5*s.* for a visit; sometimes they were 2*s.* 6*d.* and 3*s.* 6*d.* respectively, and frequently they were higher than the average. In any case it was customary to charge special fees for some services such as fractures or dislocations, which were included under the normal insurance agreement. A doctor with 2000 patients on his list could not do justice to his patients unless he employed some clerical assistance. It was difficult to give any average figure of the number of patients a doctor could visit in the course of a day; it depended largely on the nature of the practice. He agreed that a doctor should be able to give adequate treatment to 25 patients a day in an average practice.

Figures Supporting the Doctors' Claims.

Dr. Cox presented figures in support of the doctors' case. He said that the British Medical Association has experienced great difficulty in obtaining statistics from its members; it had to extract them by something approaching violence. Reducing private fees to a capitation fee equivalent, and assuming 3·8 services per insured person per annum, the returns from 13 areas showed that in only two cases was the fee below 10*s.* 6*d.*; the maximum was 14*s.* 9*d.*, and the minimum 8*s.* 7*d.* Regarding contract rates outside the insurance scheme, the figures for 40 public medical services showed that in 18 an annual fee of 13*s.* was charged for treatment and medicine; in the remaining 22 the fee varied from 20*s.* to 6*s.* 6*d.*, the latter figure referring to patients with an income limit of 21*s.* a week. There was usually an entrance fee, and special fees were charged for vaccinations, expensive medicines, and special services like fractures, dislocations, operations with anæsthetic, miscarriages, &c. As regards private contract arrangements made by individual doctors, the income limit was often £150, the patients were selected, and the services restricted. The fees varied considerably. Out of 55 cases from all parts of the country, the adult capitation rate varied from 7*s.* to 18*s.*; only seven were under 10*s.* In 13 contract arrangements made exclusively for the police, the rate varied from 11*s.* to 20*s.* The contract rate in respect of Post Office employees had been varied to accord with the National Insurance capitation rate, and was 11*s.* 6*d.* including medicines. For the colliery districts, where contract practice was common, the weekly rate worked out at a capitation fee of 9*s.* 7*d.* in Scotland and 7*s.* 8*d.* in England.

Points from Statistics.

Prof. A. L. Bowley explained some points arising out of the statistical evidence of the doctors' case. In working out the figures for the 1920 arbitration he had taken account of the special circumstances existing—for example, the scarcity of certain food-supplies, the high prices, and the inelasticity of professional incomes, and he had accordingly assumed a considerable economy in the individual doctor's budget. In 1923 there was not the same need for economy, in the national sense, and the reasons for writing down the cost of living in 1920 were no longer all applicable. This explained why the 1920 and 1923 computations did not fit closely into each other. The broad result of his calculations was that the doctor's expenses for 1923 were nearly equal to that for 1920.

Mr. M. L. Gwyer, solicitor to the Ministry of Health, suggested that it would be helpful if figures could be prepared for 1920 and 1923 computed on the same basis.

Support from the Medical Practitioners' Union.

Dr. Gordon R. Ward made a statement in support of the case submitted on behalf of the Medical Practitioners' Union. He said that in the opinion of his union it was most important that regard should be had to the quality as well as to the quantity of medical practitioners engaged in insurance practice. There had been a falling-off in doctors' incomes derived from their private practices; this was due to a variety of causes, such as the financial stringency of the middle classes, the raising to £250 of the income limit under the Insurance Acts, the increase of clinics and of hospital treatment, and the general improvement in public health. He suggested that it was a time when the remuneration from insurance practice should be increased rather than reduced. A higher rate of remuneration was also demanded by the increased range and complexity of the services required from insurance practitioners. As instances of the additional work and responsibility which the insurance doctor had to shoulder, Dr. Ward noted the increased services to hospital patients, prophylactic treatment, the treatment of allergic disease, insulin, and psychotherapy. Further, there were the grave and burdensome conditions under which the insurance doctors were obliged to accept service, including an elaborate penal code. In reply to the Chairman, Dr. Ward stated that in his opinion the average daily number of visits paid by a doctor was about 12; for his own district (Sevenoaks) it was 11·5–14.

The Case for the Ministry of Health.

Mr. Gwyer, in presenting the case on behalf of the Ministry and the Secretary for Scotland, stated that the Department, too, had approached the question impartially. They had not sought to find the cheapest rate for which they could get an insurance medical service. The capitation fee put forward by the Ministry represented, in their opinion, one for which a good average service was likely to be obtained. The Minister proposed to offer no evidence as to the quality of the service which had been given in the past. While reserving the right to call rebutting evidence at a later stage, if necessary, they accepted the past service as efficient, although, perhaps, capable of improvement.

A strictly scientific method of determining the doctors' rate of payment was probably impossible to find; one could only try several methods, and if approximately similar results were obtained those results were probably correct. All the Ministry's tests had resulted in a figure of approximately 8*s*. 6*d*. While the Ministry did not suggest that the Civil Service bonus figures were entirely comparable with the doctors' remuneration, they regarded them as being reasonably comparable for the purpose of showing the relative increase and decrease; the Ministry had used these figures only as an analogous ratio of reduction. With reference to the Time-rate Equivalent, the Ministry had arrived at the conclusion that the value of the insurance work of a doctor may be regarded as being roughly one-half of his practice. This did not mean that he necessarily earned as much from private practice as from insurance practice, but the Ministry suggested that it was a reasonable assumption that he could do so if other patients were available and were ready to go to him. The department had undertaken a careful examination of the advertisements which had appeared in certain medical papers offering medical practices for sale, and it had been found that there was a singular relation between the number of insured persons on the doctor's list and the income stated to be derived from the practice. In a large number of cases it was £1 per insurance patient; sometimes it was 30*s*. or even £2. The minimum fee in many cases was stated to be 2*s*. 6*d*.

At this stage the Court adjourned, the Chairman announcing that the Court would sit on the 21st to consider the evidence of the approved societies.

MONDAY, JAN. 7TH.

When the Court reassembled on the 7th, Sir Thomas Neill stated that the approved societies would prepare their case by the 19th. Mr. Gwyer, continuing the presentation of the Ministry's case, stated that approximately 50 per cent. of insurance doctors had under 900 insured persons on their list. Reverting to the Time-rate Equivalent, it must be understood that the capitation fee was a method of remuneration for part-time only; no doctor was occupied only with insurance practice. For the purpose of converting the fee into its time equivalent it was, however, necessary to consider how much of the doctor's time was taken up by a given amount of insurance work. Although this could not be gauged with scientific accuracy, the Ministry's calculations had been made with great care from actual records kept by doctors whose panel patients totalled three-quarters of a million. If it were not possible for a doctor to give adequate treatment to more than 25 patients a day, as had been suggested, it was difficult to understand the figures which appeared in the sale advertisements of practices where the number of insurance patients alone was not infrequently stated to be 3000, while the gross income of the practices was in all cases at least double the income derived from panel patients. A capitation fee of 8*s*. 6*d*. represented a fee of 2*s*. 5*d*. per service rendered; taking into account that this excluded the cost of medicines, cost of collection, or loss through bad debts it was practically equivalent to a fee of 3*s*. in private practice. The doctors' case made a comparison between the figures for 1913, 1920, and 1923, but it was not stated that the main increase in the doctors' work and responsibility since 1913 had resulted from the 1920 Regulations, and had, therefore, existed at the time of the 1920 arbitration, when the profession had agreed to the reduced capitation fee. The range of service had, since 1920, only been extended as regards the administration of anæsthetics. As regards the references in the doctors' case to the increase in the forms of certificate, two of the additional certificates had been asked for by the doctors themselves as tending to relieve them of work, and for a third they might demand extra payment.

The Time-rate Equivalent.

Dr. J. Smith Whitaker, a senior medical officer to the Ministry, gave evidence as to the time-rate equivalent. This method, he said, was first mentioned in a document issued in October, 1919, by the British Medical Association, and in 1920 a considerable part of the doctors' argument had proceeded on that basis. The Ministry had felt that it was necessary to relate the capitation rate to something which was commonly understood, and the test of time-rate payment was of this nature. The Department did not concern themselves with what the doctor might do in the time not devoted to insurance practice, but they were entitled to calculate the time occupied by the work for which the doctor received payment out of the Insurance Funds. It was said that the method of investigating the time equivalent and the accuracy of the records on which the calculations were based were imperfect; but very great care had been taken in this matter. The Regional Medical Officers had received very full instructions, and only the statistics of those doctors who were known to keep careful records had been taken; even so, the Ministry had rejected any records which showed an exceptionally low rate of attendances. The records were examined for towns and practices of all sizes, and, before coming to their final decision, the Ministry had the assistance of the Government Actuary's Department. Having regard to the fact that this investigation had established the figure of 3·5 services per insured person per annum, he submitted that the Court should not accept a higher figure unless it could be substantiated by equal evidence. Statistics showed that 50 per cent. of the insured population pass through the doctors' hands every year, but only from 25 per cent. to 30 per cent. of these made sickness benefit claims; in other words, only one-half of the patients attending a doctor needed certificates. The figures in the Manchester and Salford districts (where the insurance doctors were paid on an attendance basis) showed that only 0·5 per cent.—1 in 200—of the services rendered were "special" services, such as night visits, minor operations, fractures, or dislocations. He considered that a doctor could do all the work arising in connexion with an insurance list of 2000 and yet give an equal amount of time to other professional work without overworking himself. He would regard a doctor's whole time as 2400 hours a year—i.e., eight hours on 300 days a year. Two thousand patients would require about 24 services a working day; of these services eight would be visits and 16 would be consultations. A capitation fee of 7*s*. 9*d*. was at the rate of a net income in the neighbourhood of £1200 for whole-time work, a fee of 8*s*. 6*d*. would give £1330, while 10*s*. 6*d*. would give a net income of £1640.

In reply to questions by the Chairman, Dr. Smith Whitaker said that in his opinion about ten patients could be seen at the surgery in the course of an hour and in urban areas three or four visits an hour could be paid. He thought that, broadly speaking, 48 services a day, giving ten minutes for each, was a fair estimate, and that £665 represented a fair remuneration for half of the doctor's time. It was true that the Manchester and Salford figures showed 4·35 services per patient per annum, but it must be remembered that the remuneration was there reckoned on an attendance basis.

The Chairman expressed doubt whether 10 consultations per hour, or 48 services a day, allowed sufficient time to the doctor.

Dr. H. J. Neilson, a Divisional Medical Officer of the Ministry, gave evidence as to his experience of insurance practice in Nottingham from 1913 to 1915. He had worked with a partner and four assistants and the total panel of insurance patients numbered from 7000 to 8000; in addition he did more private work than insurance work. His experience was that even a doctor working comparatively slowly could manage eight visits and 16 consultations in half his time. Only about 25 per cent. of the cases treated were new cases. He worked about seven hours a day.

Dr. Brackenbury said that, on the witness's statement, he did not see why six doctors should have been necessary to deal with from 7000 to 8000 insured persons.

In reply to Dr. Ward, the witness admitted, amidst laughter, that he had been known by the nickname of "The Scotch Express."

Dr. B. A. Richmond, Regional Medical Officer of the Ministry, gave similar evidence regarding his practice in Bermondsey from 1900 to 1914. He worked the practice with five partners and there was a list of between 7000 and 8000 insurance patients, in addition to an extensive private practice. In the course of nine and a half hours' work, it had been possible for one doctor to see 40 patients at the surgery and to pay 20 visits; of these about 25 surgery attendances and five visits would relate to insured persons.

Dr. Brackenbury, having elicited the fact that 200 maternity cases were also dealt with in the course of the year, felt a difficulty in understanding how they were fitted in with the other services described by the witness, and he wondered what would happen in such a practice in times of epidemic or other stress.

Statistical Side of the Ministry's Case.

Mr. E. J. Strohmenger, C.B., Accountant-General to the Ministry, in giving evidence on the statistical side of the Ministry's case, said that, had a deduction been made, as was suggested, in respect of the pensions and other rights enjoyed by Civil servants, it would, as regards the material income limits, have made a difference of only ¾*d.* on the capitation fee. He criticised the conclusions drawn by the Insurance Acts Committee from Prof. Bowley's figures. They put the doctor in a relatively much more favourable position in 1924 than in 1920. Taking only two items, clothes and personal expenses, while Prof. Bowley showed the same percentage increase over 1914 for both years, he suggested that the cost of clothes had decreased 30 per cent. and personal expenses had decreased by 15 per cent. since 1920. He could not agree to the conclusion that, in spite of the admitted fall in prices, the cost of living for the doctor had remained practically the same. Even the moderate amendments which he suggested to Prof. Bowley's figures showed a fall approaching 20 per cent. in the expenses for 1923—a fall closely approaching that in the Civil Service bonus scale. If a capitation fee of 11*s.* was fair in 1920, then the figure for 1923 should certainly be no higher than 8*s.* 6*d.*

Sir Gilbert Garnsey stated that the figures for 1920 and 1923 in the doctors' case had now been worked out on the same basis, with the result that 1923 showed a fall of 36 points instead of 7 points as in the figures shown in the doctors' case.

Disciplinary Action.

Mr. L. G. Brock, assistant secretary to the Ministry, said that it had been suggested that the disciplinary control exercised by the Ministry over insurance doctors was so arduous that it should be taken into account in determining the appropriate capitation fee. In fact, during the past four years only five doctors had been removed from the Medical List by the Minister; three others had been allowed to resign; and of three other doctors threatened with removal two had been removed from the Medical Register by the General Medical Council, and one had died; 14 representations for the removal of a doctor had not been upheld; while in five cases a pecuniary penalty only had been inflicted. During the same period, out of 1331 cases dealt with by the Medical Service Subcommittees a pecuniary penalty had been inflicted in only 324 instances. In two exceptional cases the penalty had been £1000 and £500 respectively; otherwise the amounts had been under £100, except in ten cases where that amount had been withheld. No penalty was inflicted until the doctor had been given an opportunity of making representations. The withholding of grant was not a fine or penalty in the ordinary sense of the word; it was the recovery of money which should not have been paid to the doctor because he had not earned it.

The Chairman said that the number of cases against doctors appeared very small having regard to the total number of doctors in insurance practice.

Dr. Brackenbury said that his Committee had not, in any part of their case, objected to the disciplinary control with which Mr. Brock had dealt. Their objection was directed solely to the elaborate certification rules, which had no parallel in private practice.

Club Practice in Scotland.

Mr. J. Jeffrey, secretary to the Scottish Board of Health, gave figures relating to club practices in Scotland. An agreement had been signed in 1919 which applied to the whole mining industry and affected 140,000 to 150,000 workers and 400,000 dependents. The system was that the workers (who were insured under the Insurance Acts) paid a flat rate contribution for the provision of medical treatment to their dependents. The payment was 3½*d.* a week without medicine and 4½*d.* with medicine. Women and children under 16 paid half rates. In the steel and iron industry there was a scheme affecting 8500 workers and 23,000 dependents. The rate here was 4½*d.* a week with medicine, apprentices and boys on low wages paying 1*d.* The average number of dependents covered by each contribution was two and a quarter, and this represented a capitation fee of 7*s.* 1*d.* with medicine or 5*s.* 6*d.* without medicine.

The Court adjourned until 11 A.M. on the 8th.

The King has sent a contribution of £100 to the funds of the Mental After Care Association for Poor Persons convalescent or recovered from Institutions for the Insane, Church House, Dean's Yard, Westminster, London, S.W.

DUBLIN NATIONAL CHILDREN'S HOSPITAL.—The board of the National Children's Hospital, Dublin, has speedily taken steps to organise a staff for the hospital, after the regretted death of Sir Lambert H. Ormsby. Mr. Trevor N. Smith, who had for some time acted as physician to the extern department, is confirmed in that post. Dr. G. E. Nesbitt is appointed visiting physician, and Sir W. Taylor and Sir W. I. de C. Wheeler have been invited to accept the duties of visiting surgeons.

ROYAL INFIRMARY, GLASGOW.—The annual meeting of the managers and nursing staff was held on New Year's day, and was attended by representatives of the other hospitals and of the civic authority. Mr. M. W. Montgomery, the Lord Provost, in his opening address referred to the baronetcy recently conferred upon Sir Donald MacAlister. He spoke warmly of the high standard of proficiency to which professional nursing had attained. Mr. James Macfarlane, chairman of managers, also thanked the nursing staff for their help, and announced that arrangements had been made for extending the quarters available for their accommodation. He referred to the treatment of diabetes in the institution with material manufactured in the laboratory of Prof. Noël Paton, and stated that he foresaw the addition of a biochemical laboratory to the infirmary, to control this treatment and to investigate other similar problems. The financial situation was outlined by Mr. T. Warren. The ordinary income had increased during the year from £80,964 to £82,827, and if legacies and special contributions were added the total became £115,251. On the year's working they had been able to place to their capital account £6212. He noted that receipts had increased from £48,564 in 1899, to £151,910 in 1923. A final sum of £30,000 was to be received shortly from the trustees of Miss Schaw.

INSULIN IN THE TROPICS.

To the Editor of THE LANCET.

SIR,—Statements have appeared recently in the press that insulin is unstable in the tropics and has been found to have lost activity on arrival in India. Experiments have been carried out which show that the reports to the effect that insulin is not resistant to tropical climatic conditions should be accepted with considerable reservation so far as "A.B." insulin is concerned. A sample from a batch of "A.B." insulin was heated to a temperature of 95° F. for a month, the activity being carefully determined both before and after the treatment. The result of this careful test showed that insulin "A.B." brand had retained its activity without any detectable loss.

Further testimony to the stability of "A.B." brand insulin is afforded by the following facts. We have had returned to us from India two bottles of our insulin "A.B." brand. This insulin was part of a batch which had been reported as having lost activity in India. We have had the contents of one of the bottles re-tested here, utilising for this purpose a bottle which arrived back in a half-empty condition, as we considered that this would be the most stringent test. The figures obtained showed with remarkable agreement that the activity was exactly the same as when the batch was first issued, two and a half months previously, in spite of the fact that this insulin was sent out without any precautions as to cold storage during its journey to and from India, nor, so far as we are aware, was kept in cold storage while in India.

An interesting fact which may throw some light upon the reports of loss of activity in India is that contents of the same bottle when tested in India did not reduce the blood-sugar of the rabbits to anything like the same extent as we found it to do here before and after going to India. Four times the amount which reduced the blood-sugar to the limit (i.e., 0·042 per cent.) in England only reduced the blood-sugar to 0·062 in India. None of the rabbits in India went into convulsions, while on one-half the dose our rabbits went into very severe convulsions—one of them, indeed, being so severely convulsed that the life of the rabbit was with difficulty saved. These results suggest the possibility that rabbits in India do not give the identical quantitative reaction observed in temperate climates, owing to climatic conditions, the nature of the food administered, or some such variant. These striking and apparently conclusive tests afford very satisfactory evidence of the stability of "A.B." insulin in the tropics.

We bring the foregoing information to the notice of your readers, in order that the benefits of the insulin treatment may not be unnecessarily withheld from diabetic sufferers in the tropics.

CARDIAC DYSPNŒA.

To the Editor of THE LANCET.

SIR,—Permit me to acknowledge the kindly and interesting answer of Dr. Claude Wilson to my rather hastily written letter, a revised proof of which, on account of the holidays, did not reach you in time. The effect of a morphia injection in paroxysmal dyspnœa is so dramatic that we take less note perhaps of its solace in the burden of that more ordinary dyspnœa which to such patients makes night a horror. And the good effects soon become apparent, not only in the immediate relief, but also in a larger field of repair; in a better air entry, increasing flow of urine, steadier rhythm of the heart, and subsiding hepatic and abdominal congestion. It is hard to be sure, but I think that the injection of morphine is more effectual than opium, though for secondary reasons one may occasionally prefer opium—e.g., in the form of Dover's powder. Opium is more apt to foul the tongue and to constipate the bowels. I agree that omnipon appears more expedient than opium. Paroxysmal renal dyspnœa, as in primary contracted kidney, is so terrible a fight that one cannot refrain from injection of morphia, though I suppose we use it at greater risk. Happily in this way I have met with no mischance. And when with "cardiac kidney" uræmic symptoms appear, the injection may be used with confidence. It is surprising to see how with the cardiac relief these consequential uræmic states clear up, and the kidneys return to their natural use.

Before closing, may I plead with Dr. Wilson for precision in the use of our terms, and protest against the use in science of colloquial phrases, or at any rate against contentment with them. The term "cardiac asthma" is to be deprecated for many reasons. It is very misleading, especially to the student who is led to confuse two opposite attitudes of the thorax. In asthma the respiration is held in arrest, in cardiac dyspnœa it is violently active. A few days ago Lord Crewe protested against the English lack of precision in language, and against the defence that such and such a phrase is in common use and so cannot be resisted. In business affairs, he said, we may be satisfied with a "thereabouts," but not in science or letters; that we need more of the Greek and French "esprit de précision," more care for definition. In common conversation we may be forgiven if we call a whale a fish; but we should be surprised to see such laxities in a scientific journal.

I am, Sir, yours faithfully,

Cambridge, Jan. 6th, 1924. CLIFFORD ALLBUTT.

ON SOME USES OF DIGITALIS.

To the Editor of THE LANCET.

SIR,—I am very desirous not to misconstrue Dr. G. A. Sutherland and would therefore quote again from him: "I am one of those humble unbelievers who has hitherto failed to find *any* drug, which will act directly and beneficially on the cardiac power of contraction" (italics mine). I now learn from his letter in the Jan. 5th issue of THE LANCET that he uses the word *directly* in the strict pharmacological sense of immediate contact action, thus excluding action through the nerves, whereas I was using it in the common dictionary sense of an uninterrupted sequence of cause and effect. Had this matter been clear to me I should not, of course, have instanced the use of ammonia when applied to the nostrils, and I withdraw it therefore. But now, having accepted his pharmacological definition, what am I to say, when, on my production of a *pharmacological* example of the direct action of ammonia upon the isolated frog-heart, he accepts in one breath, "all the laboratory proof" I want, and in the next blows his acceptance to the winds in the following sentence: "The saddening thing is to see a clinician accepting the results of laboratory experiment as applicable to the treatment of diseased persons, without any attempt to test them carefully at the bedside." Is that a just remark to have made when I had actually prefaced my pharmacological instance by quoting Prof. G. B. Halford's *clinical* experience of the value of the intravenous injection of ammonia in the heart failure (collapse) of snake-bite? Such injection has, until recently, furnished our nearest approach to direct action upon the heart, and this clinical experience was in accord with the pharmacological finding. No, Dr. Sutherland need not mourn on my account, in this respect, for I am fully alive to all the difficulties which beset the transference of laboratory results to clinical medicine, and elsewhere have expressed myself quite clearly on that point. After this remark of his one reads further on with not a little surprise the following words: "No one appreciates the value of pharmacological work in the laboratory more than myself."

I conclude my argument with another piece of clinical work, citing Dr. Bodon's paper (THE LANCET, March 24th, 1923). I cannot go into this now, but would strongly advise all those interested in the subject to consult the original article, which, to my mind, is very convincing. This much, however, I would say here, that did Dr. Bodon's case stand alone it could not be ignored, and that taken together with the other evidence adduced, it makes out the strongest case for immediate intracardiac injection in cases of death from heart failure. I would go further and say that it makes a perhaps stronger case for intracardiac injection to anticipate death, other means having failed. Need one say that a great harvest of successes will not be expected from this method when thus applied to those who are *in extremis* through disease; in the case of sudden death from accident or in the course of an operation, where the vital powers are unexhausted, the method should promise much more.

To conclude, I am sorry that Dr. Sutherland finds my closing remarks provocative and I hope he will accept my assurance that they were not intended to be personal, but to apply rather to the general attitude adopted by a modern school of cardiologists, no doubt quite sincerely: I refer to the question of the advances made in the clinical use of digitalis. What I have said amounts to this, that in my opinion the rules laid down by Dr. George Balfour for the clinical administration of digitalis, some 50 years ago, have not been appreciably advanced since. Dr. Sutherland outdoes me and goes even further back—namely, to Dr. Withering, as the "father of digitalis therapy," and he quotes in evidence a fine piece of observation of the latter, which, by the way, is also quoted by Dr. Balfour. Dr. Withering, therefore, has had his reward; but no one would say that between that date 1785 and the date of Dr. Balfour's teaching, the use of digitalis had not made great advances in selection of case and precision of dosage. Why in Withering's day the differentiation of the dropsies into cardiac and renal had not even been made. But to praise the past does not mean to belittle the present, and for Sir James Mackenzie's labours and achievements I have the highest admiration, even though I be not able everywhere to follow his conclusions.

I am Sir, yours faithfully,

Jan. 7th, 1924. HARRINGTON SAINSBURY.

ON THE HUMANITY OF METHODS OF SLAUGHTER.

To the Editor of THE LANCET.

SIR,—I think most medical men will agree with Dr. Leonard Hill (THE LANCET, Dec. 22nd, 1923, p. 1382) that practically no pain is caused by the throat cutting of animals if both carotids are at once severed as in the Jewish method. I trust, however, that discussion is not to be side-tracked on the advantage or disadvantage of the Jewish method, as no doubt, whatever the result of the discussion may be, the Jewish method will continue to be used by Jews and will not be adopted by English butchers.

To my mind, what calls for immediate reform is the common method of slaughter of oxen by the pole-axe. Dr. Hill rightly states that "the pole-axe is not a certain method in the case of restive animals and in the hands of inexperienced slaughterers." May I go further and say that it is not a certain method in the hands of the most experienced, mis-hits even with them being not infrequent, with resultant intense pain to the animal which often bellows in agony. I strongly advise medical officers of health to concentrate on the immediate abolition of the pole-axe. In Brighton the free bullet has been used in the slaughter of over 3000 beasts since the new by-laws were introduced, and we have had no approach to an accident and no complaint as to the keeping properties of the meat.

I write because I see before us a long discussion on the Jewish methods of slaughter, and the effect of the various methods of slaughter on the keeping properties of meat. However interesting and valuable these discussions may be, they should not delay the immediate adoption of by-laws forbidding the use of the pole-axe. Our first duty is to prevent unnecessary suffering, and this admittedly will occur from time to time and in revolting fashion so long as the pole-axe is in use.

I am, Sir, yours faithfully,

DUNCAN FORBES,

Jan. 3rd, 1924. Medical Officer of Health, Brighton.

THE BONE MARROW AFTER EXPERIMENTAL SPLENECTOMY.

To the Editor of THE LANCET.

SIR,—Apropos of the changes in the bone marrow of normal animals after splenectomy, a subject annotated in your issue of Dec. 8th, 1923 (p. 1254), permit me to state that observations begun by Dr. J. H. Musser and myself shortly after the termination of the war [1] lessen the differences between Dr. Johnstone's conclusions and those reported by Drs. Pearce, Frazier, and myself in our work on the spleen and anæmia. This portion of our spleen work, by the way, was done by Drs. Pearce and Pepper and was first reported separately.[2]

In regard to the facts observed, the earlier work on dogs showed slight changes in the bone marrow of seven dogs between the twenty-fourth and eighty-fourth days after splenectomy, then no observations four and five months after splenectomy and more marked changes from six to 32 months after splenectomy. In our later observations on monkeys (which were controlled in some instances by preliminary and intercurrent biopsies on the femoral bone marrow of the splenectomised animals and nodectomies, &c., on the controls), marked cellular hyperplasia was found four and a half and five months after splenectomy (though it had been absent before splenectomy) and slight two and a half months after; and in two other animals was found to be still marked at 24 and 27 months after splenectomy. The difference, then, between Dr. Johnstone's and our findings is chiefly a matter of degree. He found "an increased production of red blood cells clearly observable on the average, within four weeks after splenectomy, which gradually increases to the maximum about the end of the twelfth week." We found slight cellular hyperplasia beginning in dogs about the same time, and most marked in the only two monkeys examined near the time of his maximum increase. We also were able to extend the period in which hyperplasia is known to exist to more than two years. When the different conditions of the experiments are taken into account (different species of animals, rib v. femoral marrow, &c.), it is perhaps surprising that even greater differences were not encountered.

In regard to the conclusions to be drawn, I should now be inclined to agree with Dr. Johnstone that "the marrow which follows splenectomy is probably secondary and compensatory to the anæmia which follows removal of the normal spleen," although it must always be borne in mind that increased cellular content of the bone marrow does not necessarily mean increased hæmopoiesis. Also bone-marrow studies are always necessarily incomplete (unless all the bones of the body are studied), because it is often possible to get a marked hyperplasia in the marrow of one bone and none in an adjacent bone—e.g., femur and tibia—or much less even in another part of the same bone. We have always, therefore, used the upper third of the femur as a basis for bone-marrow studies and would recommend that some such standard site be used by all bone-marrow investigators. The reason for the persistence of the cellular hyperplasia remains to be

[1] Arch. of Int. Med., 1923, xxxi., 686.
[2] Jour. of Exp. Med., 1914, xx., 19.

explained. If it is "an expression of the law of regeneration in excess," then there should be a correspondingly increased amount of blood destruction, detectable by quantitative urobilin estimations, which, as far as I know, has never been demonstrated. More probable seem earlier explanations of ours that it is partly at least due to non-hæmopoietic cells, concerned with the functions of the missing spleen, such as the breaking up of effete erythrocytes and utilisation of their products.

The complex problems of splenic functions have seemed to some recent writers to be so hopelessly obscure, that I have ventured to attempt to explain discrepancies that are more apparent than real. In the same way, an apparently adequate explanation has been offered, in the article in the *Archives of Internal Medicine* previously referred to, of the apparently contradictory blood pictures found by different investigators after splenectomy.

I am, Sir, yours faithfully,

EDWARD B. KRUMBHAAR, M.D.,
Director of Laboratories.

Philadelphia General Hospital, Dec. 20th, 1923.

GASTRIC ULCERATION.

To the Editor of THE LANCET.

SIR,—I read with regret the leading article under the above heading which appeared in your columns on Dec. 29th last. With regret, because, in my opinion, the article contains statements which cannot be substantiated upon critical examination, and because the article as a whole tends to convey a false impression of the present-day position of the therapeutics of simple ulcer of the stomach and duodenum.

It is usual, in discussions where the opinion of surgeons and physicians is divided, for the former to contrast their best results with those which follow the average, or less careful, forms of medical treatment; physicians, on the other hand, will tend to overemphasise the disastrous consequences of incompetent surgery. From your columns we have reason to expect a more judicious examination of any such problem. But on what authority do you state that "it is without exaggeration to say that the medical mortality from perforation and hæmorrhage is vastly greater than that incidental to surgery, which in a very high percentage of patients leads to a permanent cure"? To describe the deaths which follow perforation and hæmorrhage as a "medical mortality" is quite unjustified. A large series of post-mortem records which I have recently examined discloses the facts that (1) many of such deaths occur in patients who have had neither symptoms nor treatment of any kind before the final catastrophe; (2) that in not a few of these cases perforation or hæmorrhage had occurred subsequent to surgical treatment. Are such to be included in the "medical mortality"?

In the same series it was brought out that the deaths from shock or complications, occurring as the direct result of surgical intervention, whilst considerably less numerous than those following perforation, were far more frequent than those due to hæmorrhage. Where, then, lies your justification for saying that the "medical mortality" is "vastly greater"? Is such a statement "without exaggeration"? It is well to quote Sir Berkeley Moynihan's magnificant series of cases, in which there has been no operative death for many years, but it is perhaps injudicious to do so without emphasising the important fact that this series is a tribute not only to the skilful technique of that distinguished surgeon, but even more to the care with which he has selected those patients well able to withstand the shock of operation. All who have studied the question carefully are agreed that when gastrectomy is performed with less discrimination, when those cases with large ulcers attached to the pancreas or liver are not treated by jejunostomy, the operative mortality is a formidable one. So long as surgeons confine their main attention to the less serious degrees of ulceration their results must tend to be satisfactory; when, on the other hand, extensive forms of the disease are treated radically the result is very different from what the readers of your leading article are led to imagine.

The references to medical treatment in this article are, I believe, equally unfair. Physicians do display a certain hesitancy in "withdrawing the curtain of the abdominal wall" whenever they wish for precise information as to the progress of a patient; but even surgeons are inclined to accept the evidence of the X rays and of the patient himself when once their operation is performed and all is going well; and, if such standards are to be accepted in either case the experience of those physicians who have given special attention to these patients is again very different from what is suggested in your article. In March, 1922, I had occasion to summarise my views on the treatment of gastric ulcer, the subject having been recently debated by a joint meeting of physicians and surgeons at the Royal Society of Medicine. I suggested that the correct attitude of the physician or general practitioner when confronted by a case of gastric ulcer should be as follows:—

1. To treat immediately all sources of sepsis in the mouth and naso-pharynx.
2. To select without delay the cases in which surgery is indicated. These include: (*a*) all cases with chronic pyloric obstruction; (*b*) all cases which have relapsed after a course of thorough medical treatment; (*c*) all cases with a history extending over many years; (*d*) all cases with large ulcers adherent to surrounding structures, and practically all cases in which a test-meal is retained in the stomach for more than six hours; (*e*) all cases where economic position makes prolonged medical treatment impossible.
3. To treat the remaining cases medically, the main lines of treatment being: (*a*) to secure physiological rest for the stomach; (*b*) to neutralise hyperacidity; (*c*) to continue treatment for a sufficient time to procure genuine firm healing; (*d*) to protect the patient against relapse.

I believe that this opinion, to which I adhere to-day, contains no bias against the expert abdominal surgeon; and the fact that it received strongly expressed approval from Dr. W. J. Mayo, of Rochester, U.S.A., confirms me in this belief. But I would add that if my opinion has had any tendency to increase the incidence of reckless abdominal operations, as I feel your leading article may do, then I would have done better not to have written it. It is surely not right that the same journal which has published Dr. E. I. Spriggs's account of "Sixty-five cases seeking relief after short-circuiting operations" should now imply that gastric surgery has reached a position wherein failure is almost unknown; nor can I harmonise the general impression conveyed by your present article with the conclusions expressed by such authorities as Dr. N. A. Nielson or Prof. Knud Faber, of Copenhagen, which were published in your columns, or commented on with approval, within the last 12 months.

Granted that surgery can cure many cases where purely medical treatment has failed, and that in other cases cure may follow surgical treatment rapidly, whilst medical treatment is laborious, I am bound by my experience to emphasise that the death-rate after major operations on the stomach remains a serious one, and that there is an equally serious percentage of cases in whom surgery has not led to permanent cure. The withdrawal of the "curtain of the abdominal wall" is often the prelude to legitimate drama, but in an appreciable number of cases to tragedy of the grimmest description.—I am, Sir, yours faithfully,

Devonshire-place, W., Jan. 7th, 1924. T. IZOD BENNETT.

To the Editor of THE LANCET.

SIR,—With reference to the leading article on this subject in your issue of Dec. 29th last, one could not emphasise too strongly the dangers of such a clear cut statement as: "Surgery seems definitely to have established itself as the only effective treatment for gastric ulcer." If the problem was so easy to solve, much discussion might have been spared to members of the profession who are daily made more uncertain by the contradictory opinions expressed by experts of

high standing. It is true that medical treatment can cure many patients at the expense of iron discipline and also that it fails in a debatable number of cases to prevent hæmorrhages, perforation, stenosis, and cancer. But it is equally sure that surgery entails an added immediate and remote death possibility and is unable in another percentage of cases either to cure or avert recurrence.

Surgery further decisively aggravates a few cases and rarely creates a fearful danger—namely, gastro-jejunal ulcer. This disaster certainly occurs in less than 5 per cent. of operated cases, and those who have not had the misfortune of witnessing the sad plight of one of these patients should read descriptions such as given by Erdmann (American Annals of Surgery, vol. lxxiii., pp. 436–39) or of the hundreds widespread in the Austro-German literature. I believe that any doctor afflicted with recent peptic ulcer would then hesitate to entrust his life even to one of those exceptionally highly specialised surgeons until medical treatment had been intelligently tried. A well-known surgeon, who suffered from duodenal ulcer, was operated on by a French professor who will leave a name for his research on lymphatics of the stomach. Simple gastro-enterostomy was performed and jejunal ulcer appeared in a few months. The most experienced operator in Europe then resected the diseased stoma, performing an extensive gastrectomy terminated by a polya, in barely few weeks a fresh marginal ulcer appeared with fatal results!

Cases of this kind are not unique. There is not even the slightest consensus of opinion between operators like Moynihan, Pauchet, Haberer, Kümmell, W. Mayo, Balfour as to the wisest operative processes. While some of these advocate gastrectomy, others are conservative, and two who strongly recommended excision ten years ago now reject it. This suggests that matters are not so smooth as some surgeons would make us believe. It is difficult to admit that extensive systematic gastrectomy upon unselected cases including men above 50 and adherent ulcers of the lesser curvature will ever be performed with a death-rate under 5 per cent. or more.

Extensive gastrectomy with its higher primary mortality does not even confer those guarantees from jejunal ulcer expected by some masters; more than eight cases have been reported in the German literature and I know of several others. It is admitted, on the other hand, that from 25 per cent. to 10 per cent. (Balfour) of gastro-enterostomies are failures, and this means that a cruel infirmity then aggravates an already difficult position. If the claims of some in favour of this operation are justified, how is it that surgeons like Flint (THE LANCET, Sept. 8th, 1923, p. 508) defend gastro-duodenostomy, which is condemned in turn by others? Is it even well proved that surgeons have the opportunity of following over many years such a majority of their patients as to estimate beyond dispute their own methods? In THE LANCET of Dec. 22nd Walton describes a dyspeptic syndrome of young women, accompanied possibly by sharp hæmatemesis without appreciable organic lesions. Now if operative interference is blindly undertaken on the suspicion of recent ulcers, is it not at the risk of sad mistakes?

Finally, the argument of the unavoidable diet against medical treatment is unintelligible because dietetic restriction is quite as compulsory after any type of operation. It is not reasonably possible to attack the principle of surgery when it attempts to deal with incurable peptic ulcer, but a return to its indiscriminate use as soon as a case is diagnosed with mere probability cannot resist searching criticism based upon facts.—I am, Sir, yours faithfully,

Paris, Jan. 2nd, 1924. Dr. E. V. MISRACHI.

*** The gastric ulcer for which surgery and surgery alone claims to be effective is the chronic ulcer, and although this was implied in our article it might have been stated more explicitly. Dr. Izod Bennett's selection of cases in which surgery is indicated defines the common ground between two branches of the medical profession. On each side there are disputed territories.—ED. L.

Obituary.

SIR JOHN TWEEDY.

THE whole of the medical profession will have learned with regret of the sudden death on Friday last, Jan. 4th, of Sir John Tweedy, while all the senior members of the staff of THE LANCET have reasons for feeling the occurrence as a personal loss.

Sir John Tweedy was the son of Mr. John Tweedy, of Stockton-on-Tees, where he was born in 1849. He was educated at Elmfield, York, and University College, London, proceeding from the College to the hospital, on whose staff at the time the notable figures were the great Sharpey, William Jenner, John Erichsen, Sydney Ringer, Charlton Bastian, Walshe, Russell Reynolds, and Henry Thompson, while many of his contemporaries succeeded to places on the staff. He took the diplomas of the Royal Colleges in 1872, proceeding to the F.R.C.S. some four years later, and from the first showed the direction which his scientific work would take, for in 1871 he published in

SIR JOHN TWEEDY.

these columns a note on Stellation of the Normal and the Cataractous Crystalline Lens. A sequel to this paper, published in 1874, was accompanied with drawings representing enlarged views of the stellate lines on the front of the lenses in one of the cases, and attracted a good deal of attention.

His professional experiences from the beginning were roughly divided into two, the first rising from the intensive study of ophthalmology at the Royal London Ophthalmic Hospital at Moorfields, and the second from his appointment as editor of THE LANCET "Mirror of Hospital Practice." He maintained his connexion with University College Hospital by holding the post of assistant dermatologist, and the clinical experience thus gained was published as a section on diseases of the skin in the earlier editions of Roberts's Text-book on Medicine. But at Moorfields he used to the full his great opportunities of becoming a leading ophthalmologist. He followed his early publications with other useful and practical papers dealing with the physiology and anatomy as well as the surgery and therapeutics of diseases of the eye, and even before his appointment in 1879 as assistant

surgeon to Moorfields he had established considerable private reputation. He was appointed ophthalmic surgeon to that hospital and to the Great Northern Hospital in the same year, 1878, and in the ensuing period contributed largely to Heath's Dictionary of Practical Surgery, where he wrote the articles "Cornea" and "Sclerotic," and Quain's Dictionary of Medicine, where he wrote, among others, the articles "Hemeralopia" and "Nyctalopia." Clinical articles appeared in THE LANCET and elsewhere on operative procedure and the employment of various drugs, and he also wrote occasionally on his special subjects in THE LANCET, where, however, Brudenell Carter and Henry Power were senior members of the staff. In 1881 he was appointed assistant ophthalmic surgeon to University College Hospital, his senior being J. F. Streatfield, whom he succeeded as full surgeon in 1888, while other members of the full staff included some of his teachers whose names have been enumerated, and Frederick Roberts, Prof. Thane, Marcus Beck, Vivian Poore, Gowers, and Sir Rickman Godlee. From 1888 until 1904 he was professor of ophthalmology at University College, being also for a large period of the time surgeon to Moorfields.

His early and long connexion with THE LANCET introduced him, at first perhaps not very usefully, to the leaders of the profession at the very beginning of his career, but such was his obvious honesty and fairness that the members of the hospital staffs, who in the 'seventies and 'eighties still resented the attitude of the paper towards their class, were converted largely by him into hearty coöperators, making the weekly account of hospital activities inclusive and valuable. And the general outlook upon surgery which the systematic visiting of all the operating theatres gave him from the very date of his first obtaining qualifications ensured that his attitude towards his specialty should be always of the broadest as well as of the most practical kind; years later he bore witness to this in his Hunterian oration before the Royal College of Surgeons of England, when he insisted that all good specialism must be founded on good general education. During his term of editorship of "The Mirror" he became an intimate friend of Dr. James Wakley who edited THE LANCET between the years of 1862 and 1886, and through the last decade of that period Tweedy not only contributed the weekly résumé of hospital surgery and many articles in which a wide range of classical knowledge was employed, but he was also largely responsible for the utterance of the editorial views on the constitution of the Royal College of Surgeons of England. Consequently it was as a reformer that Tweedy obtained his first seat on the Council of the College, to which he was elected in 1892. His election disclosed among the Fellows of the College an unexpected sympathy with the claims of the Members, as always advocated in THE LANCET, and those who know the history of the movement which was then in existence for forwarding those claims know also that success would probably have attended the wise and conciliatory attitude which was being taken by the protagonists and supported in these columns by Tweedy. How those who wished to move quicker hampered all progress forms no part of any obituary notice of Tweedy, save that the following should be stated. Within the Council he was perfectly prepared to stand by all that he was known to stand by before his election, but he was not willing to be the spokesman of those who desired to take up a different ground. On the Council of the College he soon obtained a prominent position, because it had become clear to his colleagues that he had the story of the constitution at his finger's ends, that his actions were always scrupulously fair, and that he stood in no fear whatever of the arbitrary manners of certain of his seniors, who undoubtedly regarded his election as a protest against themselves. After just over 11 years' service on the Council, Tweedy was elected President of the College not only at the unusual age of 54 but on the first ballot. He served as President for three years, was given the honorary fellowship of the Royal College of Surgeons of Edinburgh, and the degree of LL.D. by the University of Edinburgh in 1905, and in 1906 received the honour of knighthood.

The qualities which had obtained for Tweedy such signal and prompt recognition at the Royal College of Surgeons were exhibited in many other public capacities, for his services were in keen demand wherever organisation and administration were required, it being recognised that he took no post in an honorary or ornamental capacity, but gave always of his best to the furtherance of the objects aimed at. In addition to remaining attached in a consulting capacity to his various hospitals, he was a trustee of the Hunterian Museum, and a member of the Medical Consultative Board of the Navy. He was President of the Ophthalmological Society at the same time that he was President of the Royal College of Surgeons—a unique distinction; he was at different times President of the Medico-Legal Society, of the Medical Defence Union, and of the Royal Medical Benevolent Fund, while he was a member of King Edward's Hospital Fund for London, where he sat on the distribution committee as member, and later as chairman, for 14 years, and brought a first-hand familiarity of London hospital problems to the discussions. He was a trustee and for some time treasurer of the Medical Society of London, a trustee of the London and Counties Medical Protection Society, and a member of the Council of the Imperial Cancer Research Fund. He was a first-class Latin scholar and had a sound knowledge of Greek, and the results of this interest which he took in classical literature he often employed in public utterances, such as the first Thomas Vicary lecture delivered before the Royal College of Surgeons, and the Annual Oration at the Medical Society of London, both of which excellent discourses were published in our columns and displayed the speaker not only as a classicist, but as possessing sound and varied knowledge on medical history. In recognition of this knowledge he was elected Master of the Worshipful Company of Barbers, at the sex-centenary celebration of the Company.

We have said enough to show that in Sir John Tweedy not only the medical profession but the whole of society has lost one whom it could ill afford to spare. He had been in delicate health for some time, but his death must have been unexpected to all save his immediate entourage. At the Centenary Dinner of THE LANCET, save for an increased deafness, he appeared to his friends to be in his usual health, the laboured respiration, whose cause was never discovered and which made strangers think that he was a serious invalid, having been common to him for the greater part of his life.

Sir John Tweedy married Mary, daughter of Mr. Richard Hilhouse, and had two sons and one daughter. Lady Tweedy is widely known to all the medical profession for her indefatigable and successful work in connexion with the Royal Medical Benevolent Fund Guild.

ROGER ALAN BIRDWOOD, M.D. CAMB.

Dr. R. A. Birdwood, late medical superintendent of infectious hospitals under the Metropolitan Asylums Board, London, died on Jan. 2nd, in his seventy-third year. Born in Bombay in 1851, he was one of the younger of the 14 children of General Christopher Birdwood, Deputy Commissary-General of the Bombay Army and sometime Commander of the Poona Brigade. Dr. Birdwood was educated at the Dollar Academy, at the Blackheath School for the Sons of Missionaries (his maternal grandfather being the Rev. Joseph Taylor, of the London Missionary Society), and at King's College, London. Unsuccessful in an effort made, at the minimum age, to gain admission to the I.C.S., he went with a scholarship to Peterhouse, Cambridge, and graduated M.A. He took his M.D. degree from Guy's Hospital, and after a short period of work under the Metropolitan Asylums Board went out to South Africa for service in the Zulu Campaign. There he distinguished himself in medical service and received the medal and clasp. Returning to London,

Dr. Birdwood was appointed house surgeon to the Gravesend Infirmary, and by his energies secured the provision of a separate ward for children. In 1884 the Asylums Board appointed him medical superintendent of the hospital ships. He was an able administrator and a skilled organiser, and in 1892 he accepted the responsibility of planning and furnishing the North-Eastern Fever Hospital at Tottenham, where his experience, combined with his personal qualities, his energy, and his optimism, were the chief factors which welded the institution into an efficient whole. Some years later he was entrusted with a similar task in the Park Fever Hospital at Hither Green. There he remained in charge for 18 years, during which time he carried out its conversion to the children's service, and later its re-conversion for infectious diseases. The Metropolitan Asylums Board often sought his advice and assistance on questions of policy, and it was on his initiative that its hospitals were brought into use for medical instruction. When he retired in 1915 the Board, as a recognition of his exceptional professional services, added five years to his actual period of service for the purpose of computing the superannuation allowance.

An old friend and former colleague at Tottenham Fever Hospital, Dr. F. M. Turner, sends the following appreciation of Dr. Birdwood's work: "He was a man of high ideals both in medicine and other matters. Many of the causes that he took up and of the opinions that he advocated were not popular at the time, but have been since justified by experience or by being later adopted as orthodox doctrine. His advocacy of the policy of sending all small-pox cases out of London to the hospital ships at Dartford was accompanied by the prophecy that we should then get rid of small-pox in London except for fresh importations, a prophecy that has come true. His view that alcohol was a poison and did more harm than good in severe infectious fevers was based on his own observations in small-pox cases. Many a lecture did his junior medical officers receive if they prescribed it. He was not quite consistent, for when he had a patient dying he would himself often order champagne. And if this doctrine is still an unsettled question, the statistics as to the decline in the alcohol prescribed in both the London general hospitals and the fever hospitals, which have been often quoted, show that his views, unorthodox in 1890, are very close to the average medical opinion at the present time. Into the vaccination controversy Birdwood was necessarily drawn. He held that one vaccination mark is quite as good a protection as three or more, and used always to vaccinate in one place only at the small-pox hospital ships. This view is not yet accepted by orthodox authorities, but the M.A.B. statistics show that it is much nearer the truth than the common opinion that two vesicles give twice the protection of one. In politics Birdwood was a Radical and in favour of most progressive movements. He favoured the entry of women into the medical profession, and there were usually women doctors on the staff at Tottenham. He always strove for the right as he saw it, and strove hard."

Touching his personal qualities, a former senior assistant medical officer at the Park Hospital writes of his old chief: "Three of Roger Birdwood's characteristics are green in my memory. His intense personal interest and keenness to help in the work and future career of the men whom he trained, his hatred of conventionality and humbug, and his love for children, animals, and flowers. To Birdwood there was no such thing as 'routine work.' Every apparently unimportant detail was to him a matter of vital importance to the welfare of the hospital which he ruled and loved so well, and much of his day was spent in personal conversation with officials of every grade on the importance of their work and the effect which it had on the welfare of the patients. To his assistant medical officers he was a hard and sometimes irascible taskmaster, but he was also a sympathetic friend and a real inspiration and driving force. He never accepted a view simply because it was popular or in the text-books, and yet he was a far more severe critic of his own opinions than of the other views which he often so scathingly derided. His criticism often hurt for the moment, but it was always followed by a glimpse of the warm heart underneath and was ever constructive. Birdwood was really, though perhaps unconsciously, often in advance of his times. In his criticism, for instance, of the conventional attitude towards the antitoxin treatment of diphtheria, which we A.M.O.'s were apt to regard as an article of faith, he forestalled much of the subsequent work on anaphylaxis, though he was apt to regard the pathological laboratory as a funk-hole in which lazy medical officers used to prolong the after-breakfast pipe. His reputation as an intuitive clinician of rare skill and a born administrator was well known to those who had the privilege of working under him. He was also a well-beloved master and friend."

Dr. Birdwood's only son, Lieutenant H. F. Birdwood, of the Flying Corps, was killed early in 1916 in an air fight over the enemy lines on the Western Front.

JAMES LAMOND LACKIE, M.D., C.M., F.R.C.P. EDIN.

THE death took place during his sleep in the early morning of Jan. 5th of Dr. J. Lamond Lackie, physician to the Royal Maternity and Simpson Memorial Hospital, Edinburgh. Dr. Lackie was 56 years of age and apparently in excellent health. He was cut off in the full vigour of his professional activities.

Dr. Lackie was born at Montrose, where he received his early education. Later he attended the arts classes at Aberdeen University for a short time. In 1885 he came to Edinburgh to commence his medical studies, and, after an exceptionally brilliant career as an undergraduate, he qualified with first-class honours in 1889, when he was awarded the James Scott Prize in obstetrics. It was the gaining of this prize which determined his future career. In 1894 he took his M.D. degree with honours, and in 1896 became a Fellow of the Royal College of Physicians of Edinburgh. After filling several junior hospital appointments in Edinburgh and a short period of general practice in Ventnor as assistant to Dr. J. G. S. Coghill, he returned to Edinburgh as assistant to Sir Halliday Croom. His association with Sir Halliday Croom, for whom he had the greatest admiration, influenced him in many ways, and to that influence no doubt he owed much of his skill and proficiency.

At the time of his death Dr. Lackie held many important appointments. He was one of the senior physicians at the Royal Maternity and Simpson Memorial Hospital, senior gynæcologist in Leith Hospital, and senior gynæcologist in the Hospital for Women at Archibald-place. He was also a valued member of the Council of the Royal College of Physicians, and was examiner in midwifery and gynæcology to the Universities of Edinburgh, Aberdeen, Durham, and St. Andrews. In November last he resigned office as President of the Edinburgh Obstetrical Society, and his presidential address,[1] which discussed the advances in obstetrics and gynæcology in his time, showed the masterly grip he had on his subject and the breadth of his outlook. He was President of the British Gynæcological Congress which met in Edinburgh last year, and the unqualified success of that meeting was in large measure due to his genial personality and the esteem in which he was held by his professional brethren. His practice as an obstetrician and gynæcologist was extensive, and his special knowledge and skill were often sought and always valued by his fellow practitioners. Dr. Lackie inspired confidence, esteem, and affection in all his patients and in all with whom he came in contact. His interests outside his professional life were many, and his tall, commanding presence,

[1] THE LANCET, Nov. 24th, 1923, p. 1158.

his cheery, optimistic personality brought him many friends. He was a keen golfer and curler, and fond of shooting. One might say, briefly, that he was a man widely and deservedly loved.

Dr. Lackie is survived by his wife, son, and daughter, to whom will go out the sympathy of his many friends.

Medical News.

UNIVERSITY OF LONDON.—A Course of Three Advanced Lectures in Hygiene on the Influence of Improved Town Planning and Housing in Public Health will be given at University College, Gower-street, London, W.C., by Prof. John Robertson, at 5 P.M. on Jan. 18th, Feb. 1st, and Feb. 15th. The first lecture will deal with existing conditions which prejudicially influence health in the housing and town planning of English towns, the second lecture with standards of accommodation and of environment which are essential for good health, and the third lecture with the results to be achieved, the question of cost, and the propaganda necessary to obtain the best results. At the first lecture the chair will be taken by Prof. H. R. Kenwood. The lectures, which will be illustrated with lantern slides, are addressed to advanced students of the University and to others interested in the subject. Admission is free, without ticket.

ROYAL SOCIETY OF MEDICINE.—The next social evening will be held on Jan. 16th, at 8.30 P.M., when Fellows, Members of sections, Associates and their friends will be received by the President, Sir William Hale-White, and Lady Hale-White.

Owing to the illness of Dr. Arnold Chaplin, whose lecture had been previously announced, Sir Arthur Keith will give a short lecture, entitled Punch as an Anthropologist, at 9 P.M. It will be illustrated on the epidiascope. The library will be open, and various objects of interest will be shown, including an exhibition of hand-loom silks and pottery.

ROYAL INSTITUTION.—The hour of the afternoon lectures at the Institution has been altered this year from 3 to 5.15 P.M., except on Saturdays when the hour remains 3. This decision will be welcomed by many who have hitherto been unable to attend these interesting lectures. The courses begin on Tuesday next, with the first of two lectures by Prof. W. E. Dixon on Drug Addictions.

CHELSEA CLINICAL SOCIETY.—A meeting will take place at the Club Room, St. George's Hospital (entrance through main doors during rebuilding), on Jan. 15th at 8.30 P.M., when a discussion on the Treatment of Functional Nervous Disorders will be opened by Dr. S. A. Kinnier Wilson.

MEDICO-LEGAL SOCIETY.—A meeting will be held at 11, Chandos-street, Cavendish-square, London, W., on Jan. 15th, at 8.30 P.M., when a paper will be read by Sir Francis Newbolt, K.C., on Evidence of Resemblance in Paternity Cases, which will be followed by a discussion.

GUILD OF PUBLIC PHARMACISTS.—A lecture will be delivered by Mr. E. W. Morris, house governor of the London Hospital, on the Future of Voluntary and Municipal Hospitals, at 17, Bloomsbury-square, on Jan. 16th, at 8 P.M. Dr. H. L. Eason will preside.

MANCHESTER ROYAL INFIRMARY.—The Old Residents' Club will hold a dinner at the Midland Hotel, Manchester, on Feb. 5th. Any old resident who has not received a notice is asked to communicate with the hon. secretaries of the Club, at the Royal Infirmary.

AMERICAN MEDICAL ASSOCIATION: ANNUAL MEETING.—The date of the next annual gathering of this Association has been fixed for June 9th to 13th, 1924. All the sessions will be held on the Municipal Pier at Chicago.

ROYAL MEDICAL BENEVOLENT FUND GUILD.—A concert in aid of this Guild will be given by the Stock Exchange Male Voice Choir on Jan. 22nd, at 8 P.M., at the Wigmore Hall, Wigmore-street, London, W. Further particulars and tickets may be obtained from the Hon. Organiser, Mr. C. Godwin, 25, Austin Friars, E.C. 2.

LONDON NEUROLOGICAL CLINIC.—The sixth annual dinner will be held at Princes' Restaurant, Piccadilly, London, W., on Jan. 26th, at 7 for 7.30 P.M. Tickets 15s. each. The guest of the evening will be Lord Dawson. Past and present members who wish to be present should notify the treasurer, Dr. E. F. Pratt, 15, Clarges-street, W., before Jan. 19th.

ROYAL INSTITUTE OF PUBLIC HEALTH.—A Course of nine lectures on Tuberculosis will be delivered in the Lecture Hall of the Institute, 37, Russell-square, London, W.C. 1, on Wednesdays at 4 P.M., from Jan. 16th to March 12th. Prof. S. Lyle Cummins will give the opening lecture on Tuberculosis: How and When is it an Infective Disease? and the subsequent lecturers will be Dr. G. Lissant Cox, Sir Henry Gauvain, Dr. S. Vere Pearson, Dr. P. C. Varrier-Jones, Dr. Marcus S. Paterson, Dr. A. C. Inman, Dr. B. T. J. Glover, and Dr. G. B. Dixon.

DUBLIN (83) GENERAL HOSPITAL ANNUAL DINNER.—The annual dinner of the members of the Dublin Units who served at 83 (Dublin) General Hospital in France in 1917–18 was held on Jan. 5th, at Mills' Hall, Dublin. Sir William Taylor, who organised the units, presided, and there were about twenty present. The members entertained as guests General R. H. S. Sawyer and Prof. A. Fullerton, who had been D.D.M.S. and consulting surgeon respectively in the Boulogne area when the hospital was working, and Mr. A. Miller, registrar of the Royal College of Surgeons in Ireland.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, Jan. 15th.

GENERAL MEETING OF FELLOWS: at 5 P.M.
Ballot for election to the Fellowship.

PATHOLOGY: at 8.30 P.M.
Communications, &c.:
Mr. R. J. Gunther: Demonstration of a case of Arteriosclerosis in a Crocodile of the Mesozoic Age.
Mr. J. K. Clarke: Bacteriology of Dental Caries.
Mr. A. Fleming: Accuracy of Measurements in Capillary Tubes.

Wednesday, Jan. 16th.

HISTORY OF MEDICINE: at 5 P.M.
Paper:
Lieut.-Colonel H. A. L. Howell, R.A.M.C. (Ret.): Medical Services at the Battle of Waterloo.

WAR.
Members of the War Section are cordially invited to attend the above meeting.

SOCIAL EVENING.
The next Social Evening will be held on Wednesday, Jan. 16th, at 8.30 P.M., when Fellows, Members of Sections, Associates, and their friends will be received by the President, Sir William Hale-White, and Lady Hale-White, at 8.30 P.M.
Owing to the illness of Dr. Arnold Chaplin, whose lecture has been announced on previous notices, Sir Arthur Keith has kindly agreed to give a short lecture in his place, entitled Punch as an Anthropologist, at 9 P.M. It will be illustrated on the epidiascope.
The Library will be open and various objects of interest will be exhibited. Music, light refreshments, and smoking.

LIBRARY.
On this evening the principal Reading Room will be closed at 5 P.M., but readers will be accommodated in other rooms.

Thursday, Jan. 17th.

DERMATOLOGY: at 5 P.M. (Cases at 4 P.M.)

Friday, Jan. 18th.

ELECTRO-THERAPEUTICS: at 8.30 P.M.
Papers:
Dr. C. Beresford Alexander: Electro-therapeutic Methods in the Treatment of Fractures.
Dr. Martin Smart: Injuries to Muscles and Joints and their Treatment by Graduated Contraction.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.
MONDAY, Jan. 14th.—8 P.M., Pathological Meeting. Specimens. Dr. H. G. Butterfield will give a demonstration of his method and apparatus for micro-photography.

HUNTERIAN SOCIETY.
MONDAY, Jan. 14th.—(At the London Mansion House.) Sir J. Thomson-Walker: Hunterian Oration: Infections of the Urinary Tract due to the *B. coli communis*.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 11, Chandos-street, W.
THURSDAY, Jan. 17th.—8.15 P.M. (preceded by a demonstration at 7.45 of Various Dysenteric Conditions) a paper on Local Immunity in Infectious Diseases, by Prof. Besredka, of the Pasteur Institute, Paris, will be read (in English) by his colleague, Dr. Harry Platz.

ROYAL INSTITUTION OF GREAT BRITAIN, Albemarle-street, W.
TUESDAY, Jan. 15th.—5.15 P.M., Dr. W. E. Dixon: Drug Addictions. (Lecture I.)
FRIDAY.—9 P.M., Prof. H. E. Armstrong: The Scientific Work of Prof. Sir James Dewar.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.
WEDNESDAY, Jan. 16th.—4 P.M., Prof. S. L. Cummins: Tuberculosis—How and When is it an Infectious Disease?

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.
MONDAY, Jan. 14th, to FRIDAY, Jan. 18th.—NORTH-EASTERN FEVER HOSPITAL. Wed. and Sat., 11 A.M., Dr. F. Thomson: Diagnosis and Treatment of the Acute Infectious Diseases.—ST. PETER'S HOSPITAL FOR STONE. Mon., 2 P.M., Mr. Andrews: Injuries of the Urinary Organs; Tues., 2 P.M., Mr. Joly: Urinary Calculi and Calculous Disease; Wed., 2 P.M., Mr. Morson: Tumours of the Urinary Tract; Thurs., Mr. F. J. F. Barrington: Non-Tuberculous Infections of the Urinary Tract: Fri., 2 P.M., Sir John Thomson-Walker: Urinary Obstruction (this lecture will be given at the Royal Society of Medicine); Sat., 2 P.M., Mr. Harkness: Urethritis in the Male.—THE INFANTS HOSPITAL. 2 P.M., Clinical Demonstrations each day. Mon., 4 P.M., Dr. Eric Pritchard: Modification of Cow's Milk; Tues., 4 P.M., Dr. Mackay: Therapeutic Effects of Ultra-Violet Ray (illustrated); Wed., 4 P.M., Dr. MacCormac: Diagnosis of Skin Diseases in Infants; Thurs., 4 P.M., Dr. D. Paterson: Convulsions; Fri., 4 P.M., Mr. Tyrrell Gray: Pyloric Stenosis.—WEST END HOSPITAL FOR NERVOUS DISEASES, at 73, Welbeck-street, W. Mon., 2 P.M., Dr. H. Carlill: Practical Points in Everyday Neurology; Tues., 5 P.M., Mr. Laming Evans: Orthopædic Treatment of Nervous Diseases. Thurs., 5 P.M., Dr. Carlill: Tabes Dorsalis; Fri., 1.30 P.M., Sir James Dundas-Grant: Labyrinthine Tests.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.
MONDAY, Jan. 14th.—10 A.M., Mr. Maingot: Surgical Pathology. 12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Mr. Bishop Harman: Eye Dept.
TUESDAY.—12 noon, Dr. Burrell: Chest Cases. 2 P.M., Mr. Sinclair: Surgical Out-patients. 2.30 P.M., Mr. Tyrrell Gray: Surgical Wards.
WEDNESDAY.—10 A.M., Dr. Saunders: Medical Diseases of Children. 12.15 P.M., Dr. Burnford: Medical Pathology. 2 P.M., Dr. Pernet: Skin Dept.
THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Dept. 12 noon, Mr. Simmonds: Demonstration of Fractures. 2 P.M., Dr. Scott Pinchin: Medical Out-patients.
FRIDAY.—10 A.M., Dr. Drummond Robinson: Gynæcological Operations. 12 noon, Mr. Endean: Venereal Diseases. 2 P.M., Mr. Banks-Davis: Throat, Nose, and Ear Dept.
SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.
Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

UNIVERSITY COLLEGE, Gower-street, W.C.
FRIDAY, Jan. 18th.—5 P.M., Prof. J. Robertson: The Influence of Improved Town Planning and Housing in Public Health. (First of three lectures.)

CANCER HOSPITAL, Kensington, S.W.
WEDNESDAY, Jan. 16th.—4.30 P.M., Mr. C. E. S. Phillips: Electricity in the Service of Medicine.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.
THURSDAY, Jan. 17th.—4 P.M., Dr. Heald: Treatment of Poliomyelitis by Diathermy.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.
TUESDAY, Jan. 15th.—5 P.M., Dr. H. W. Barber: Lupus Erythematosus.
THURSDAY.—Chesterfield Lecture, 5 P.M., Dr. W. Griffith: Eczema.

QUEEN CHARLOTTE'S LYING-IN HOSPITAL, Marylebone-road, N.W.
THURSDAY, Jan. 17th.—Dr. C. H. Roberts: Ante-partum Hæmorrhage.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES. (At 3.30 P.M.)
MONDAY, Jan. 14th.—(At the Hospital for Women.) Mr. A. L. Robinson: Genital Prolapse.
TUESDAY.—(At the Maternity Hospital.) Mr. Leith Murray: Ante-partum Hæmorrhage.
WEDNESDAY.—(At the St. Paul's Eye Hospital.) Mr. H. Bywater: Methods of Examination of the Eyes.
THURSDAY.—(At St. George's Skin Hospital.) Dr. F. H. Barendt: Skin Cases.
FRIDAY.—(At the Eye and Ear Infirmary.)

Appointments.

STEELE, R. V., M.B., B.S. Durh., has been appointed Post Office Medical Officer for Camden Town Division (N.W. Head District).

Royal Northern Hospital: GRAHAM, G., M.D. Lond., F.R.C.P. Lond., Physician (with charge of In-patients); BEATTY, C. C., M.B., B.S. Lond., M.R.C.P. Lond., Physician (with charge of Out-patients); MCCOY, H. A., M.B., Ch.M., Assistant Radiologist; ROSE, W. G., M.B., B.S. Lond., Resident Medical Officer; MASON, G. A., M.B., Casualty officer; MACONIE, A. C., M.B., B.S. Lond., and HEMBROW, C. H., M.B., House Surgeons.

Certifying Surgeons under the Factory and Workshop Acts: MACKINLAY, W. H., M.B., C.M. Edin. (Redcar); BODY, T. M., L.R.C.P. Lond., M.R.C.S. (Middlesbrough); MOORE, P. W., M.B. Lond. (Coggeshall); FIRTH, I. G. M., M.B., Ch.B. Aberd. (Osmotherley); STREATFIELD, P. W., L.R.C.P. Lond., M.R.C.S. (Waltham Abbey).

Vacancies.

St. Pancras Dispensary, 39, Oakley-square, N.W.—R.M.O. £225.
St. Thomas's Hospital Medical School.—Demonstrator of Anatomy. £400.
Salisbury General Infirmary.—H.S. £200.
Stoke-on-Trent Education Committee.—School Dentist. £500.
Stoke-on-Trent, North Staffordshire Infirmary.—H.S. £200.
Torquay, Local Education Authority.—Asst. Sch. M.O., &c. £600.
Wakefield, Clayton Hospital.—H.S. £200.

The Chief Inspector of Factories, Home Office, London, S.W., announces vacancies at Newark, Littlehampton, Clackmannan, and Oakengates.

Births, Marriages, and Deaths.

BIRTHS.

CRANSTOUN.—On Jan. 3rd, at Perry Hill, Worplesdon, the wife of Gordon Cranstoun, M.B., B.Ch., of a son.
ROSS.—On Dec. 27th, 1923, at Patna, India, the wife of Lieut.-Colonel William C. Ross, I.M.S., of a daughter.
WEBSTER.—At 1, Carden-terrace, Aberdeen, on New Year's Day, the wife of A. U. Webster, M.C., M.A., M.B., Fraserburgh, of a daughter.

MARRIAGES.

MILLS—KELSEY.—On Dec. 8th, 1923, Lieut.-Colonel Bernard Langley Mills, M.D., F.R.S.E., R.A.M.C. (retired), to Leila Susanne, widow of Reginald Kelsey and daughter of the late G. S. Cardew, M.D., J.P., Inspector-General of Hospitals, Bengal Army.

DEATHS.

BAMFORD.—On Jan. 4th, at The Hermitage, Uttoxeter, Charles Robert Bamford, M.R.C.S., L.R.C.P., aged 64.
BIRDWOOD.—On Jan. 2nd, at Twickenham, Roger Alan Birdwood, M.D. Camb., in his seventy-third year.
FISHER COCK.—On Jan. 4th, at Ashford, Middlesex, Morris Fisher Cock, M.R.C.S., L.R.C.P., aged 67.
GWYNN.—On Dec. 29th, 1923, at St. Mary's House, Whitchurch, Shropshire, Charles Henry Gwynn, M.D. Edin., M.R.C.S. Eng., aged 69.
LAMOND LACKIE.—At 7, Randolph-crescent, Edinburgh, on Jan. 5th, very suddenly, James Lamond Lackie, M.D., F.R.C.P.E.
SANKEY.—On Jan. 4th, at Woodstock-road, Oxford, Julius Ottaway Sankey, M.R.C.S., L.R.C.P.
TWEEDY.—On Jan. 4th, suddenly, after a short illness, John Tweedy, F.R.C.S., LL.D., Kt., aged 75.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

ALCOHOLISM IN VARIOUS SOCIAL CLASSES.*

BY H. M. VERNON, M.D. OXF.,
AUTHOR OF "INDUSTRIAL FATIGUE AND EFFICIENCY," ETC.

THE recent publication of the supplement to the seventy-fifth annual report of the Registrar-General exhibits the incidence of alcoholism in various social classes of the community, and permits the drawing of a number of conclusions as to the factors concerned in the promotion and the prevention of alcoholism. The report, publication of which was delayed by the war, relates to the years 1910–12, and might therefore be thought to be quite out of date, but I believe that the information to be adduced will negative this view. It is true that the 1920–22 data are likely to be more instructive, as they will show the effects of the great reduction in alcohol consumption caused by high taxation and by changes in the hours of sale, but they are not likely to be published for many years to come.

The report contains 191 tables of figures, recording the mortality of various groups of men from certain specified diseases, including "alcoholism" and "cirrhosis of the liver." The deaths recorded under these headings are more strictly defined than those recorded in previous reports under the headings of "alcoholism" and "diseases of the liver," but for purposes of comparison some of the present data have been calculated on the old basis, as well as on the new one. Considering only the men who died between the ages of 25 and 65, the group of "occupied and retired males" in England and Wales, which numbered 7,852,042 individuals, showed a mortality of 4 from alcoholism and of 13 from cirrhosis of the liver, when estimated on the present scale, whilst on the old scale it was 7 for alcoholism and 16 for diseases of the liver. Since 1900–02 the comparative mortality figure (which relates to a standard population of 71,005 men, aged 25 to 65) has fallen from 1004 to 790, or 21 per cent., whilst the mortality from alcoholism and liver diseases has fallen from 43 to 23, or 47 per cent. This relatively greater improvement in the alcohol mortality than in the general mortality is a very satisfactory feature, which is likely to be maintained in the 1920–22 data, when they are published. Thus the total deaths of all males in England and Wales from alcoholism and liver diseases is stated (in "The Alliance Year Book," 1922, p. 223) to be 84 per million in 1920, as compared with 156 in 1910, and 294 in 1900. The alcohol mortality in various social classes is shown in the table:—

Alcohol Mortality in various Social Classes.

—	No. of groups averaged.	Deaths from alcohol of groups with comparative mortality of—						
		Under 600.	600 to 699.	700 to 799.	800 to 899.	900 to 1099.	1100 or more.	Mean per-centage
A	6 to 15	7(1·3)	10(1·6)	13(1·7)	15(1·8)	16(1·6)	—	1·6
B	2 to 4	7(1·2)	—	—	—	17(1·8)	28(2·3)	1·8
C	3 to 5	15(2·8)	24(3·7)	22(2·9)	—	—	—	3·2
D	2 to 6	16(3·0)	20(3·1)	23(3·0)	—	35(3·8)	—	3·2
E	2 or 3	—	—	—	—	53(5·0)	134(9·0)	7·0

Social Class.—A = Skilled and semi-skilled workmen. B = Unskilled workmen. C = Professional classes and clerks. D = Shopkeepers, &c. E = Brewers, publicans, &c.

The Registrar-General divides up the various occupational groups into eight social classes, but five of them (viz., 3, 4, 6, 7, and 8) may conveniently be classified together as "skilled and semi-skilled workmen," though I am excluding the groups engaged in the production and sale of alcoholic liquors. The other three social classes consist of "unskilled workmen," "upper and middle classes," and "intermediate," these latter consisting for the most part of shopkeepers. Some of the occupational groups are too small to yield reliable data, so I have ignored any group in which the number of deaths from alcohol (i.e., alcoholism and cirrhosis of the liver) was less than ten. This plan tends to eliminate rather too large a proportion of the more abstemious groups, but the error introduced thereby will not affect any of the arguments advanced. All the data referred to relate only to men between the ages of 25 and 65.

* An abstract of a paper introductory to a discussion before the Society for the Study of Inebriety, held in the rooms of the Medical Society of London, on Jan. 8th, 1924.

Alcoholism among Skilled and Semi-Skilled Workmen.

The combined class of skilled and semi-skilled workmen is by far the largest, so it will be considered first. The mortality of these groups from all causes varies between the extremes of 157 for gardeners and 1196 for potters, and for purposes of comparison I have split them up into the five divisions recorded in the table. The first division comprises the six occupational groups in which the comparative mortality was less than 600, and it will be seen that on an average these groups showed an alcohol mortality of 7. The next division includes the eight groups with a comparative mortality of 600 to 699, and their alcohol mortality averaged 10. In the succeeding divisions the alcohol mortality averaged 12, 15, and 16, so it follows that the alcohol mortality increased steadily as the general mortality increased. Expressed as a percentage on the general mortality, the alcohol mortality in the five divisions was 1·3, 1·6, 1·7, 1·8, and 1·6—i.e., it was practically constant.

What is the significance of the close correspondence between the two mortalities? In the first place, to what extent is the general mortality affected, indirectly, by excessive indulgence in alcohol? Evidence on this point can be obtained by comparing the causes of death in typical groups of individuals liable to excessive indulgence in alcohol with other groups who are not so liable. In order to render the comparison valid, it is essential that the groups compared should be men of similar social class, living under similar conditions as regards housing and general character of work (indoor or outdoor, light or heavy). The most suitable group provided by the Registrar-General is that of "inn, hotel—keepers; publicans; spirit, wine, beer—dealers," and for comparison purposes the group of "all shopkeepers." This includes men such as drapers, grocers, butchers, greengrocers, stationers, ironmongers, tobacconists, and chemists. From the mortalities of the two groups from diseases of the respiratory, circulatory, digestive, nervous, and urinary systems, it appears that in every instance the mortality of the publicans was 1·6 to 2·0 times greater than that of the shopkeepers. From alcoholism and liver cirrhosis it was 7·8 and 6·3 times greater, whilst the total deaths from these causes were 132 more numerous than in the shopkeepers. The total deaths from all causes were 557 more numerous, and if we deduct the deaths from alcohol, we find that the excess of deaths in the publicans which were presumably caused indirectly by alcohol come to 425, or about three times more than the direct deaths.

I have also compared two other occupational groups: these are barmen on the one hand and indoor domestic servants (other than those in hotels) on the other. They are not nearly such closely comparable groups as the previous pair, but they are the best I could find. It will be seen that the frequency of occurrence of the various diseases in barmen, as compared with domestic servants, was very variable, and ranged from 1·4 to 3·2. The total deaths from alcohol were 86 more numerous in barmen, whilst the deaths from all causes combined were 973 in excess. That is to say, the deaths due indirectly to alcohol were apparently ten times more numerous than those caused directly. This estimate differs widely from the former one, and all that we can conclude with safety is that the indirect effects of alcoholic excess are much greater than the direct effects, and are probably more than three times as great.

If, for the moment, we assume that the indirect deaths due to alcohol are ten times as numerous as the direct deaths, they still fail to account for more than a third of the rise of comparative mortality shown in the table. Thus, if comparative mortalities of 550, 650, 750, and 850 are corrected on the tenfold alcohol basis, they become reduced to alcohol-free mortalities of 473, 540, 607, and 685 respectively. Hence we must look elsewhere than to alcohol in order to account for the larger part of the variations in the general mortality of industrial workers. Evidence on this point, yielded by examining the occupational groups falling in the various divisions, suggests that the relationship between the alcohol mortality and the general mortality of industrial workers is very different from that described in publicans and barmen. Owing to the unhealthy conditions under which many of them carry on their work their general health suffers, and thereby they become readier victims to alcohol. Possibly they may indulge in no more alcohol than other men who work under healthier conditions, but may owe their greater mortality to diminished bodily resistance. On the other hand, it is probable that their reduced health makes them more ready to seek comfort in drinking, but, whatever the weight to be ascribed to these or other causes in accounting for the effects produced, there can be no doubt whatever that by improving the conditions under which industrial work is carried on, we shall reduce both the general mortality and the alcohol mortality. The better the factories are ventilated and lighted, the more

frequently changing and washing rooms are provided, whereby over-heated workers (especially miners and iron- and steel-workers) can change into dry clothes directly their day's work is over, the better will be the general health and self-respect of the men employed in industry and the greater their sobriety.

Alcoholism Among Unskilled Workmen.

The Registrar-General's class of "unskilled workmen" includes only a few and widely divergent occupational groups. Two of them, the brickmakers and the platelayers, have a comparative mortality rate of 567 and 621 respectively, and an alcohol mortality of 8 and 6. Hence they resemble the best of the skilled workers. This is owing to the fact that they lead a vigorous open-air life. The remaining groups of unskilled workmen are very different, for they show both a high general mortality and a high alcohol mortality. One division, with a comparative mortality of 900 to 957, includes coal-heavers, carmen, and cabmen and grooms. Their alcohol rates are 12, 17, and 23 respectively, and represent the same percentage on general mortality as is observed in the corresponding groups of skilled workmen. The remaining groups of unskilled workmen are not represented at all amongst the skilled, as their comparative mortality varied from 1102 to 1507, and their alcohol mortality from 22 to 35. They comprise watermen, dock labourers, messengers, and costermongers, and they are clearly of a different social class from the majority of skilled workmen, as they are not only unskilled, but they are casual workmen.

Alcoholism Among Professional Classes and Shopkeepers.

Widely as the unskilled labourers differ from the skilled, there is in some ways a greater jump still when we proceed to the other two social classes tabulated by the Registrar-General. Social Class I., comprising the "upper and middle classes," consists chiefly of professional men and clerks. Their comparative mortality figure ranges from 506 to 863, and has a distinctly lower average than that of the other social classes. In spite of this, their alcohol mortality is nearly twice as great as that of the skilled industrial workers. It will be seen from the table that whilst the alcohol mortality of the first three divisions of skilled workmen was 7, 10, and 12, that of the corresponding divisions of professional men and clerks was 15, 24, and 22. The three groups with a general mortality of less than 600 consists of schoolmasters, bank officials, and of civil service officials and clerks. Their alcohol mortality is 12, 17, and 17 respectively, so the schoolmasters alone are comparable in alcoholic restraint to the average skilled industrial worker. Best of all is the group of clergy, with a general mortality of 443 and an alcohol mortality of 4, but owing to the total number of deaths from alcoholism being less than 10, the group is excluded from my classification.

The division with a comparative mortality of 600 to 699 comprises railway officials, builders, doctors, lawyers, and artists, and their alcohol mortality is 16, 20, 27, 28, and 31 respectively. That is to say, the lawyers and doctors, whose professional duties teach them daily the evils of alcoholism, are themselves amongst the greatest sinners. The third division, whose general mortality varies from 724 to 765, comprises insurance agents, law clerks, commercial travellers, and chemists and druggists. Their alcohol mortality is 8, 24, 25, and 35 respectively. Finally, the large group of commercial clerks has a general mortality rate of 863, and an alcoholic mortality of 20. In the table this group has been put with the 700–799 division for averaging purposes.

The percentages of alcohol mortality on general mortality have an average value of 3·2 for the shopkeepers, or the same as that observed in the professional classes. It is twice the percentage alcohol mortality observed in the skilled workmen, and nearly twice that in the unskilled workmen. What are the causes of these tremendous differences? Firstly, the workmen have to pursue occupations which are chiefly of a muscular character, and are often carried on in the open air. On that account they maintain themselves in a better physical condition than the professional men and shopkeepers, who are mostly employed indoors on work which requires no muscular effort, and is frequently sedentary. Secondly, the workmen, as a class, are not so well-to-do as the professional men and shopkeepers, and can less readily afford expenditure on alcoholic liquors. However, this argument is not one of great importance, for we have seen that clerks, taken as a whole, have as great an alcohol mortality as professional men, though they are certainly less well-paid, whilst the badly paid unskilled workmen have a greater alcohol mortality than the better-paid skilled workmen.

The Effect of Drinking Spirits.

The chief reason of the difference between the alcohol mortality of workmen and of the other two classes is due, I believe, to the form of intoxicants indulged in. The workman takes his alcohol mostly in the form of beer, whilst the professional classes and the shopkeepers take theirs in the form of spirits. As spirits contain eight to ten times more alcohol than beer, it is very much easier to introduce excess of alcohol into the system. Again, spirit-drinking is easily indulged in at all times of the day by those who can afford to keep a supply of spirits at home, and, as Dr. W. C. Sullivan pointed out nearly twenty years ago, the frequent drinking of small doses is peculiarly apt to bring about chronic alcoholism, though it does not cause drunkenness. Convivial drinking, on the other hand, is very likely to lead to drunkenness, but as it is indulged in only occasionally, it is much less harmful to the system.

PUBLIC HEALTH IN BURMA.[1]

THE population of the area under registration for vital statistics in Burma numbered 10,771,190 at the census enumeration of 1921, showing an increase of 946,800 since 1911; this amounts to 9·64 per cent. The immigrants numbered 331,992 and the emigrants 303,806, the former showing a decrease of 9188, and the latter an increase of 55,821 on the previous year's statistics. The birth-rate was 29·85 per 1000, as compared with 33·78 in the previous year and 33·33 for the quinquennium; but if the latter ratio be corrected, to allow for the exaggeration due to the use of the 1911 census population as a basis of calculation, the quinquennial ratio becomes 31·67. There was a considerable difference between the ratios for Lower and Upper Burma, the former being 26·90 and the latter 34·82 in 1921; and for the quinquennium (corrected) 29·67 and 34·25 per 1000. Lieut.-Colonel C. E. Williams, I.M.S., the Director of Public Health for the province, states, however, that "the evidence of the 1921 census points to the general birth-rate in town and country being 50 per mille or above, confirming the estimates of previous censuses and the experience of officers of this department." There appears to be considerable "neglect of registration by the public and local registrars." The general death ratio for the province was 21·45 per 1000, as compared with 27·40, the corrected ratio for the quinquennium, 1916–20. In the rural areas (with a population of 9,558,291) the mortality was 19·66; in the towns (population 1,212,899) the ratio was 35·55 per 1000; among the former the ratios varied from 14·37 in Myingyan and 16·23 in Sagaing (both districts in Upper Burma), to 28·00 in Sandoway (Lower Burma) and 29·53 in Kyaukse (Upper Burma). It is noteworthy that the lowest and highest mortality ratios occurred in two rural districts adjoining each other, Myingyan and Kyaukse; in the same two rural districts the quinquennial death-rates had been 23·01 and 43·06 respectively. The ratios of death from "fever" in 1921 were 3·00 and 10·28 per 1000. Among the towns the total mortality varied from 18·38 at Yamethin, in Meiktila division, and 18·63 at Syriam in Pegu division, to 54·36 at Prome (also in Pegu division), and 73·16 at Mawlamyainggyun in Irrawaddy division; at this latter town fever, dysentery, cholera, and plague were prevalent. At Rangoon and Mandalay the birth ratios were 18·29 and 44·41 respectively; the death ratios were 35·28 and 43·27.

Infantile Mortality.

In regard to infantile mortality there has been a marked improvement. The ratio per 1000 births was 172·06, compared with 186·65 in 1920, 216·90 in 1919, and 271·24 in 1918; the ratio for Upper Burma, which had been 260·33 in 1919 (compared with 185·83 in Lower Burma), has fallen to 173·65 (compared with 170·84 for Lower Burma). "Never before has the Upper Burma ratio so closely approached that of Lower Burma." In the rural areas the mortality declined from 205·33 per 1000 births in 1919 to 177·92 in 1920, and 160·37 in 1921: in the towns from 320·99 in 1919 to 271·22 in 1920, but rose to 278·84 in 1921. Very high infantile mortality was recorded in several large towns, such as Rangoon (322·67), Mandalay (341·85), and Shwebo (458·96): but in some cases it is supposed that a large number of births (mainly female) were not registered. A child welfare endowment fund was organised at the instance of Lady Craddock, wife of the Lieutenant Governor, to coördinate the work of the societies already established, and is destined to become a valuable asset in the movement in this province. 1095 confinements were attended in Rangoon and 456 in Mandalay; there was not a single death among the mothers in these cases. At various towns in the province committees of European ladies render most valuable assistance in regard to the welfare of children, and at Taunggyi (Upper Burma) Colonel Williams "was greatly struck by the interest shown in the movement by a large number of Shan ladies and women of the labouring class."

[1] Report on Public Health Administration. Rangoon Government Press. 1922.

Infectious Diseases.

Cholera was present in all districts in Lower, and in five out of the 12 in Upper Burma, with six isolated cases in five other districts. Not a single death was reported from this cause in Lower Chindwin or Meiktila districts. The total deaths numbered 3791 (0·35 per 1000); in Sandoway district the mortality was 3·48, and in Mergui 4·50 per 1000. The ratio for towns was 0·94 in Lower and 0·09 in Upper Burma; for rural areas 0·45 and 0·09 respectively. The chief prevalence occurred in the Irrawaddy division, where serious outbreaks occurred in every district during the first five months of the year, in which period 1130 deaths occurred from this cause. "The protective influence of a pure and protected water-supply against the spread of cholera infection is illustrated by the experience of Monywa town, where outbreaks of the disease were of almost annual experience until 1916, when the water-supply scheme was completed, since which year no death from cholera has been returned from that town." There was a great reduction in small-pox, from which cause 987 deaths were returned (0·09 per 1000), against 2853 in 1920; in Lower and Upper Burma the ratios were 0·07 and 0·13 respectively; in Thaton district (Tenasserim division) the mortality was 0·42; in Mandalay 0·50; in five districts there was not a single death from this cause (Kyaukpu, Hanthawaddy, Pyapon, Tavoy, and Yamethin). Plague caused 4403 deaths (0·41 per 1000), the ratios for Lower and Upper Burma being 0·53 and 0·21 respectively: the corresponding quinquennial ratios had been 0·67, 0·70, and 0·61 respectively. Rangoon district had a mortality of 3·29 per 1000, representing 1126 deaths; for Mandalay district the corresponding figures were 0·94 and 334; and for Prome 1·64 and 609; for the whole province the death-rate from plague was 2·88 in the towns and 0·09 in the rural districts. Colonel Williams points out that there are two plague seasons in Rangoon, the first reaching its maximum prevalence in March or April, and the second in July or August; a simular incidence occurs at Prome. The causative influences or factors have not been determined: they may be connected with the presence of different species of rats or fleas, or special social or economic conditions. The chief preventive measures adopted were rat-destruction and inoculation: "both measures are optional, and neither is making much progress"; nevertheless, 471,549 rats were destroyed (405,178 in Rangoon), and 43,552 inoculations performed.

The "fever" death ratio (7·68 per 1000) compares favourably with that of the preceding quinquennium (10·83). "It is clear that the position in 1911 has nearly been regained in 1921, and that the influence of influenza in raising enormously the fever mortality ratios of the previous three years has to a great extent lapsed." In the several districts the ratios varied from 2·18 in Rangoon, 3·13 in Myingyan, and 3·94 in Ma-ubin to 16·0 in Tavoy; in the rural areas the range was from 3·0 in Myingyan to 16·61 in Tavoy, and for the towns from 2·18 in Rangoon and 2·26 in Danubyu to 15·07 at Mawlamyainggyun and 15·98 at Wakema. The statistics of death from actual malaria are available only for the towns, and these are not considered to be trustworthy. Enteric fever was reported as causing 231 deaths, but was probably much more widely distributed than would appear from the returns. There was some prevalence of influenza from time to time in all parts of the province. In towns 537 deaths were returned as due to this cause, of which 233 occurred in Rangoon and 103 in Mandalay; in rural areas 112 deaths were reported. Dysentery and diarrhœa caused 9728 deaths (0·90 per 1000); of these 8119 occurred in Lower and 1609 in Upper Burma. "There can be little doubt that deaths from these complaints are much more frequent than the Upper Burma returns indicate." In 22 jails 8896 prisoners were examined for ankylostoma infection, of whom 67·43 per cent. were found to be infected; chenopodium oil was administered in capsules with good results. The Port Health Station at Rangoon is now provided with a commodious shed for examination of all classes of passengers, and two steam disinfectors have been installed; this port now compares favourably in its health work and accommodation for passengers with anything yet accomplished in India.

Prison Administration.[2]

In the Report on Prison Administration in Burma for 1921 it is stated that there are indications that the "jail population is still steadily rising." At the beginning of the year the total prisoners in the seven central and 23 district jails numbered 15,796; during the year 45,639 prisoners were received and 45,204 discharged, the number remaining at the end of the year being 16,231. The daily average population was 16,088, of whom 15,009 were convicts; of these 135 were females. It had been found that the illicit use of tobacco was the great cause of breaches of discipline; Lieut.-Colonel H. H. G. Knapp, I.M.S., Inspector General of Prisons for the province, who forwards this report, recommended that tobacco in moderation should be allowed as a reward for good conduct. The local government approved of the suggestion, and at the Moulmein jail the experiment was tried, by allowing a cheroot once a day to well-behaved prisoners and to convict officers; the competition to get into the smokers' list was keen, and the jail superintendent stated that he had "seen nothing but good resulting from this experiment," the number of punishments in this jail falling from 683 to 211—that is, from 86·12 to 30·89 per cent. of the prison population. Colonel Knapp desires an extension of the method to some other jail to serve as a check to this experiment. The Burmese (of both sexes) are keen smokers, and "devote much energy to the congenial task of outwitting the staff, with fair success." At Prome a "jail tobacco treasury" was discovered hidden in a loft in the female ward, access to which involved a climbing feat by one of the young female convicts. In regard to the health of the prisoners, for the average population of 16,088 the average daily sick ratio was 24·06 and the mortality 16·22 per 1000; the former was higher than in any of the four years preceding (in which it varied from 15·19 in 1917 to 23·32 in 1918), but the death-rate was considerably lower (19·0, 25·59, 28·53, and 19·92 in the four years respectively). The increase in daily sick "shows that care was taken to admit those that required treatment and that the 24 hours rule was observed better than last year. This is especially true of the Rangoon jail." Colonel Knapp has no doubt good reason for this explanation of the increase in this particular instance, but it is obviously not applicable as a general proposition.

In the seven large central jails at Rangoon, Insein, Bassein, Myaungmya, Thyetmyo, Mandalay, and Myingyan, the health statistics showed very wide variations. At Rangoon, with an average strength of 2336 (not including 12 Europeans), the admissions to hospital amounted to 860·02 per 1000, the average daily sick were 38·53, and the deaths only 10·27 per 1000; at Thyetmyo (average strength 1029) the corresponding ratios were 69·00, 6·80, and 17·49. The death-rate was highest at Mandalay (25·97), and Myingyan (24·31); at Myaungmya it was only 9·83. In the 24 district jails the hospital admissions varied from 51·72 per 1000 at Sandoway and 72·99 at Kyaukpyu, to 958·51 at Prome and 1434·18 at Akyab; the average daily sick were only 7·30 per 1000 at Kyaukpyu, 6·85 at Shwegyin, and 4·20 at Magwe; at Pagan, Katha, Mogok, and Tavoy the ratios were 27·27, 27·78, 32·61, and 33·11 respectively; not a single death occurred in the jails at Mergui, Mogok, Shwebo, Taungdwingyi, Meiktila, Yamethin, or Thaton, the combined average strength of the seven jails being 718. In the other district jails the mortality varied from 6·62 at Tavoy and 6·85 at Shwegyin, to 57·55 at Paungdè, and 136·36 at Pagan. For the province as a whole the chief cause of sickness among the convicts (numbering 15,009 out of the total 16,088 daily strength) was malaria and its sequelæ, enlarged spleen and cachexia, with an admission ratio of 39·31 (590 cases), but only four deaths are returned as due to this cause (0·27 per 1000). For dysentery there were 574 admissions (38·24 per 1000) and 27 deaths (1·80 per 1000). Only four cases of cholera occurred, three at Akyab and one at Toungoo, all fatal. There has been a marked decline in tuberculous disease, "and this is the more remarkable, in that medical officers and their staffs pay greater attention to early diagnosis and segregation than formerly." The admissions numbered 180 and the deaths 52. Pneumonia, on the other hand, increased from 49 admissions and 14 deaths (presumably in 1920) to 79 admissions and 27 deaths in 1921 (all among convicts); 22 of the admissions and four deaths occurred at Mandalay. There were 41 admissions for enteric fever, with 11 deaths, 17 of the cases occurring at Mandalay, 11 at Insein, and five at Rangoon. It is stated that "typhoid is rife in Mandalay town," where 81 deaths from this cause were recorded, probably an under-estimate. Much good work is done at the Meiktila Juvenile Jail, where there was a daily average of 133 convicts under the care of a Burman superintendent. The boys are instructed in carpentry, shoemaking, sawing, and (most important of all) in agricultural work on a farm attached to the jail. The after-history of 113 cases showed that 77 were in some kind of regular work, and only seven are known to have relapsed.

HEALTH CONDITIONS IN NYASALAND.

THE European population at the end of 1922 was returned at 1499, the Asiatic at 662, and the Native at 1,185,655. During the year the health of the Protectorate was satisfactory. There were a few cases of small-pox in the early part of the year, the residue of an outbreak which occurred at Mlanje in 1921. No case of plague was reported. Fewer cases of venereal diseases were recorded than in 1921: 341 cases of yaws were treated, as against 235 in the previous year. Most of these cases occurred at Karonga; 70 rural

dispensaries were opened during 1922. These are worked by natives, who have had an elementary training in dealing with minor ailments and in dressing wounds. Although these dispensaries were open for about half the year only, their existence resulted in double the number of native out-patients being treated—39,000, as against 19,000 in 1921. The in-patients numbered about the same as in the previous year—2300. As regards Europeans, as in 1921, about 500 were treated by the medical department, and there were 15 deaths, six of which were due to blackwater fever. Malaria accounted for nearly 28 per cent. of the European illnesses. Amongst the native population eight cases of sleeping sickness were recorded. Villages infected with human trypanosomiasis were removed to a "fly-free" area. The rainy season, 1921–22, was an unsatisfactory one, as the rainfall was much below normal, and conditions of drought, followed by a scarcity of native foodstuffs, prevailed throughout the southern part of the Protectorate. A considerable amount of suffering was entailed by the famine, but there is no reason to think that the deaths from starvation were numerous. The natives bore the distress and suffering with courage and fortitude, and expressions of gratitude to the Government were received from principal headmen for the assistance rendered to them and their people. The climate of Nyasaland in its essential features is similar to that of the rest of Eastern Africa within the tropics, but it is necessarily diversified owing to variations in latitude, altitude, and general configuration of the terrain, presence or absence of rivers, forests, &c., but as a large proportion of the Protectorate lies at an altitude of 3000 feet or more the heat is not generally excessive. The south-east monsoon commences to blow strongly in September, and the first rains may be expected any time after mid-October. From their commencement to the end of December it is usual to experience violent thunderstorms and heavy precipitation in a few hours, followed by an interval varying from 1 to 15 or 20 days of intense heat. With the return of the sun from its southern limit of declination the thunderstorms diminish in intensity and frequency, and are replaced by steady rain, January, February, and March being usually the wettest months as regards duration of rainfall, as well as actual amount. After March the frequency and intensity of rainfall diminishes rapidly, and from May to September the climate is comparatively cool and dry.

DUSTLESS SWEEPING.

WE have had brought to our notice a preparation bearing the name of "Kleensweep," which, it is claimed, offers a certain and simple method of eliminating the raising of dust in the operation of sweeping floors. A few ounces of the preparation are laid in a straight line across the floor and swept along with the dust which it absorbs and entangles. One preparation is suitable for use on linoleum, wood or concrete, another for carpets. Both contain substances which exert a cleansing and disinfecting action and emit an aromatic odour that is distinctly agreeable. We have tried the preparation on floors of various kinds and consider that it would take a useful place in factories and institutions where the old-fashioned method of sprinkling floors with water or tea-leaves is employed. "Kleensweep" is sold in sacks at 11*s.* per cwt., and can be obtained from the Kleensweep Manufacturing Co., 35 to 37, Verulam-street, London, E.C. 4.

THE WELLCOME FOUNDATION.

THE Wellcome Foundation, Ltd., has recently been registered as a private limited company, with a capital of £1,000,000 to acquire from Mr. Henry S. Wellcome the well-known business of Burroughs Wellcome & Co., and the various scientific institutions founded and owned by Mr. Wellcome, who will be the governing director of the Foundation during his life. We understand that the Foundation has been formed entirely for private and family reasons, and that the conduct and management of the business will be continued on exactly the same lines as heretofore. The scientific institutions will continue as in the past under separate scientific direction.

PENSIONS TO WIDOWS OF DISABLED MEN.

THE Minister of Pensions announces a further decision of the Government in respect of claims to pension by widows of men disabled in the war, who die more than seven years after discharge or removal from duty: (1) A new Article will be inserted in the Royal Warrant providing, without any time limit, for the grant of pension at maximum rates to the widow of any pensioner whose death is certified to be wholly due to the nature or condition of his pensioned disability, such nature or condition being directly the result of his war service. The formula will cover cases of serious aggravation of a disability not directly due to war service. (2) In regard to claims made under the new Article and rejected by the Ministry of Pensions, there will be a right of appeal to the Pensions Appeal Tribunal. (3) Other cases occurring beyond the seven years' limit in which the man's death, though not wholly and directly the result of war service, was nevertheless so far connected with it as to justify some measure of compensation, will be considered. Eligibility for pension under that Article is governed by the extent to which the man was recognised during his lifetime to be disabled by war service, but the minimum limit of 50 per cent. which was laid down is now to be reduced to 40 per cent.

THE JOHN HANCOCK CARTRIDGE PEN.

THE utility and convenience of many fountain pens have often to be discounted by the troubles attending their filling. In the case of the John Hancock Cartridge Pen (Ingenuities, 23A, Old Bond-street, London, W.), a specimen of which has been sent to us for trial, filling troubles are obviated by the use of a sealed metal cartridge of special ink which is used for recharging the pen. The act of screwing in the cartridge perforates the sealed end and allows the ink to flow to the nib. Each cartridge contains sufficient ink for writing on an average 6000 words. The barrel of the pen is constructed of stout hard rubber, and an ingenious "feed" gives an even flow to the ink. A short trial of the pen seems to justify the claims of the makers that it does not leak or clog. The nibs, which are fashioned for different types of handwriting, are made of 14 carat gold, with specially treated iridium points, and the complete pen is sold in a neat box containing three cartridge refills in a pocket case, at the price of 21*s.* Packets of three refill cartridges—estimated at six weeks' supply—can be obtained for 1*s.*

INDEX TO "THE LANCET," VOL. II., 1923.

THE Index and Title-page to Vol. II., 1923, which was completed with the issue of Dec. 29th, will shortly be published. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 1, Bedford-street, Strand, W.C. 2.

An Address

ON

FRACTURES FROM AN OPERATIVE STANDPOINT.

*Being the Presidential Address delivered before the Dublin University Biological Association.**

BY WILLIAM PEARSON, M.D., B.CH. DUB., F.R.C.S. IREL.,

SURGEON TO THE ADELAIDE HOSPITAL, DUBLIN; ASSISTANT TO THE PROFESSOR OF SURGERY, TRINITY COLLEGE, DUBLIN.

NOT many years have elapsed since the subject of fractures was brought before this Association by a former president, Sir William Wheeler, in an interesting and able historical survey. Nevertheless, I have chosen it without hesitation for my address, and I feel that in doing so no apology is necessary. The study of fractures is a fascinating one, beset with difficulties and problems yet unsolved, and in recent times there is no subject which has occupied the attention of surgeons to a greater extent than that of fractures and their treatment.

TREATMENT OF FRACTURES BEFORE AND DURING THE WAR.

For some years prior to the outbreak of the Great War the problems of the treatment of simple fractures had become of supreme interest. Operative measures, rendered possible by the advancements of modern surgery, had been introduced and were claiming an increasing number of adherents. In the British Isles this position was due chiefly to the work of Sir Arbuthnot Lane, whose faultless technique and brilliant results had attracted world-wide attention. The relative merits of conservative and operative treatment were so keenly debated, and the question had reached such importance, that in 1910, following a discussion at the annual meeting of the British Medical Association, a committee was appointed by the Council of the Association "To report on the ultimate results obtained in the treatment of simple fractures with or without operation." In 1912 its report was published,[1] based on investigations of over 2900 cases of fractures of the long bones. This report merits close study; but it must suffice here to say that its conclusions, while carefully guarded, were, on the whole, favourable to operative treatment. It demonstrated clearly the close relationship between good anatomical and good functional results, and also showed that in a considerable proportion of cases both open and closed methods of treatment left much to be desired.

In America, and on the Continent also, the subject was exciting great interest, and the operative treatment of simple fractures formed one of the topics for discussion at the French Surgical Congress in 1911. Although no agreement was reached, there is no doubt that operative measures, especially those advocated by Lane, were widely practised at this period.

With the outbreak of war in 1914, when surgeons were faced with the task of dealing with overwhelming numbers of grossly infected compound fractures, fresh problems arose. It was recognised that direct fixation by operative means was not only inadvisable but dangerous in such cases; operations on the fracture were confined to those dealing with infection, and the attention of surgeons was turned once more to indirect methods of control. The great value of extension and the Thomas's splint—so long insisted on by Sir Robert Jones—became apparent; non-operative treatment was enormously improved, and excellent results were obtained in many cases which, in the early stages of the war, would have proved hopeless. Consequently, operative treatment for the fixation of fractures has largely fallen into disuse and is, I think, not employed as frequently as it should be at the present time.

In spite of all progress, it is natural that many unsatisfactory results should have followed the serious fractures of warfare. Vicious union and non-union have been common sequelæ and constitute problems with which orthopædic surgeons have been much concerned, and in which operative measures are clearly indicated in many cases. In bringing my subject before you to-night no comprehensive review is possible, and I shall confine my remarks to problems which are of general interest at the present time.

From an operative standpoint fractures may be conveniently divided into (1) recent fractures, and (2) old-standing cases. In the former, apart from infection, operation is usually undertaken for the purpose of securing accurate adjustment or "setting" of the fragments; in the latter it may be required to remedy mal-union or non-union.

RECENT FRACTURES.

In the treatment of recent simple fractures operative measures are not to be lightly undertaken. As major surgical procedures they are not devoid of risk; they possess peculiar difficulties and dangers, and should never be attempted except under favourable circumstances. Now more than ever, with the knowledge and experience gained in the war, it is safe to say that the majority of recent simple fractures can be efficiently treated by non-operative means. There remains, however, a number of cases in which such measures offer little prospect of success, and in these operation is indicated provided that by it prognosis is definitely improved. The balance between operative risk and improved outlook must always be preserved.

The selection of cases for operative treatment requires experience and judgment, and should be guided by several factors. Of these the most important are the precise anatomical features of the fracture, which can only be determined by adequate X ray examination. In this matter the coöperation of radiologist and surgeon is essential. Skiagrams which may be fully instructive to the radiologist may not convey the necessary information from the viewpoint of surgical treatment, and the surgeon himself must clearly interpret and visualise the fracture if misconceptions and errors of judgment are to be avoided. Gross displacement of the fragments is not in itself an indication for operative treatment. In many cases reduction by manipulation may be easily and rapidly effected; in others, with much overlapping of the fragments, extension may prove efficient. Doubtful cases should always receive the benefit of preliminary non-operative treatment, and the results should be confirmed by further radiograms. The age, occupation, and general condition of the patient must also be considered. Old age does not necessarily constitute a barrier to operation, but the risks are greater and the prospects of a good functional result (even after successful operation) are more remote. In children operation will be rarely indicated; non-operative measures yield a high percentage of success, and young bones are not well adapted to all forms of operative fixation. In general, extensive comminution will contra-indicate operation.

With fractures, as with other orthopædic cases, it must also be remembered that operation is but one step in treatment, and that careful post-operative supervision is necessary if successful results are to be obtained. Statistics show that with proper selection of cases the operative mortality is negligible, and the principal risks which may be urged against the operative treatment of simple fractures are sepsis and non-union. These risks are common to all methods of direct operative fixation, but in the vast majority of cases their occurrence is due to one or both of two technical errors—faulty asepsis and imperfect fixation of the fracture—and are therefore avoidable.

* The address as delivered was illustrated by a series of excellent skiagrams.

Sepsis.—The occurrence of sepsis is disastrous. At the best it means a prolonged convalescence and ultimate removal of any foreign body employed to secure fixation: while the possibilities of osteomyelitis, non-union, pyæmia, and amputation cannot be ignored. With faulty technique the risk of sepsis is increased by permanent burying of foreign bodies in the tissues. It has also been urged that, apart from errors of asepsis, the presence of a foreign body in the bone may produce suppuration, but Hey Groves[2] has shown experimentally that this is true only if fixation is insecure; and clinical experience supports this view.

Non-union.—Apart from sepsis and insecure fixation, the risk of non-union has been exaggerated. Accurate reduction and firm fixation will result in minimum callus formation—a condition paralleled by the faint scar of an incised wound which heals accurately by first intention—and only in this sense can delayed union be considered common. Consolidation of definitive callus is at all times a tardy process, and for several weeks post-operative skiagraphic appearances may simulate non-union if no provisional callus is seen. In this connexion the manner in which the periosteum is treated at operation is of some importance: subperiosteal exposure and fixation of the fracture favours the development of subperiosteal callus and minimises the risk of non-union. With good technique non-union is rare, and must then be attributed to operative trauma and interference with the blood-supply at the site of fracture. The danger is so remote that it should not be allowed to weigh unduly against operation. In a series of 58 cases of simple recent fracture on which I have operated there has been no instance of infection, delayed union, or non-union.

THE OPERATION.

The most favourable period to operate is towards the end of the first week after injury. This delay adds nothing to the difficulties, and the tissues have then become more resistant to infection. With much swelling of the limb further postponement is desirable, and operation may be performed, if necessary, even at the end of three or four weeks. In these later cases the early callus should be carefully cleared (and preserved) with the periosteum from the ends of the bone and medullary canal before the fracture is adjusted.

Reduction by open operation does not always entail the use of direct means of fixation, and where there is no tendency to recurrence of the displacement the wound should be closed without further interference. If direct fixation is necessary various methods are available, none of which is entirely free from objection or applicable to all cases. The method to be selected will depend on the individual fracture, but certain general principles must always be followed. These may be briefly summarised as: (1) detailed planning of the operation in advance by study of the skiagrams; (2) rigid asepsis; (3) free incisions; (4) careful hæmostasis; (5) accurate anatomical reduction of the fracture; (6) secure fixation; and (7) accurate closure of the wound.

The reduction of the fracture may be, and often is, the most difficult step in the operation. It is to be accomplished by manual dexterity rather than by force, and skill in the manœuvre can only be acquired by experience. Traction on the limb by means of extension is usually unnecessary, but may be employed in cases of long oblique and spiral fractures if much overlapping is present. In these cases the greatest difficulty may be encountered, and preliminary extension for some days is advisable. It should be remembered that reduction of displacement is the prime object of the operation, and nothing short of anatomical accuracy should satisfy the surgeon. Incomplete reduction is a common cause of bad results, and should be regarded as an operative failure.

METHODS OF FIXATION.

I will now refer briefly to some of the principal methods of fixation.

Plating.

Plating, or fixation by screws and plates, enjoyed much popularity at one period. In Lane's hands the method achieved great success, but owing to adverse criticisms and the number of failures reported by others it is now generally regarded with disfavour. The mechanical defects of plates and screws as a means of fixation, to which Hey Groves[3] has drawn attention, impose definite limitations to the use of the method which have been frequently overlooked, and have contributed to many failures. It is, however, a method by which excellent results may be achieved, and is, in my opinion, still the method of choice in selected cases. Failures with Lane's plates may be attributed to (1) faulty asepsis; (2) defective mechanical technique; (3) selection of unsuitable cases; and (4) inefficient post-operative treatment. Transverse and slightly oblique fractures, especially those with irregular surfaces, and certain T-shaped and Y-shaped fractures are those best suited to plating; long oblique and spiral fractures—at all times most difficult from an operative standpoint—are not well adapted to Lane's method, and are better treated by other means. My own experience with Lane's plates has been most satisfactory. I have employed them in 28 cases of recent simple fracture with excellent results. There was no case of infection or delayed union, no loosening of screws (as proved by skiagrams), and the anatomical and functional results in all cases were perfect.

Various modifications of Lane's plates have been devised, of which the most efficient are Hey Groves's bolted and pinned plates. In these the plates are secured by bolts or split pins which transfix the entire thickness of the bone. Their application is more difficult, requiring much freer exposure of the bone, and in the event of sepsis they are more dangerous and difficult to remove; but as a means of fixation they leave nothing to be desired, and may be employed in cases where additional security is necessary.

Fixation by Bands.

The majority of long oblique and spiral fractures may be efficiently treated by means of extension. Operation is rarely necessary, and their accurate reduction by open methods may be exceedingly difficult. In these cases fixation is best obtained by the use of steel bands which bind the fragments together, and the best appliance of this type is the Parham-Martin band. Two bands may be passed round the fracture, but in many cases one will suffice to secure fixation. Adams's spring clip or bands or sutures of wire may also be employed, but are less satisfactory.

Wiring.

Fixation by wiring is most useful in such cases as fractures of the patella, olecranon, condyles of the humerus, and other small detached fragments. The patella and olecranon are best secured by passing the wire transversely through each fragment, or where the upper fragment is very small the wire may be passed through the muscle immediately above. Soft iron wire is the best material for the purpose, but silver, bronze-aluminium, and "belt lacing" wire are generally satisfactory. Silver wire may gradually undergo disintregation in the tissues, and should therefore be of stout size. Like screws, wire sutures as a means of fixation exhibit certain mechanical defects, and under the influence of continuous strong muscle pull will gradually cut their way through the bone.

Intramedullary Pegs.

The use of intramedullary pegs introduces a principle which is now frequently employed in bone-grafting operations. In this method alignment is

secured by inserting a cylindrical peg of bone or ivory into the medullary canal across the line of fracture. The procedure is simple and rapid and is admirably suited to many cases of transverse fracture, especially where there is a tendency to lateral displacement of one fragment. It also possesses the advantage that the pegs are gradually absorbed and do not remain as permanent foreign bodies in the bone, but it involves considerable interference with the blood-supply of the medulla and if sepsis occurs the presence of the peg is dangerous and its removal difficult. To minimise interference with the medullary circulation and to favour union I have employed grooved pegs in preference to those usually adopted. A size should be chosen which can be thrust into the canal without undue force, and it is wise to avoid drilling if possible.

OLD-STANDING FRACTURES.

In dealing with old-standing fractures the chief conditions which demand operative treatment are mal-union and non-union. Following simple fractures such conditions should be exceptional, but many cases have followed the compound injuries of warfare and these require special consideration. Not infrequently such cases are complicated by extensive scars in the skin and muscles, associated nerve or joint injuries, and the dangers of active or latent sepsis—all of which must be considered before operative measures are undertaken. Selection is often a matter of difficulty and should be guided by three considerations: (1) The degree of functional disability present; (2) the difficulties and risks of the operation; and (3) the prospects of definite functional improvement. It is unprofitable to correct deformity if function is not improved and such results should be regarded as operative failures. By strict attention to these points meddlesome surgery will be avoided.

Mal-Union.

With rare exceptions, mal-union is due to faults in early treatment: the principal causes being primary incomplete reduction, inefficient splinting, inefficient extension, and premature removal of support whereby a recently united fracture is exposed to weight-bearing and muscular strain before consolidation is advanced. Prevention of mal-union is generally easy; its cure may be difficult or impossible. In the shafts of long bones three principal types of mal-union occur—angulation, rotation, and overlapping. Angulation occurs most frequently in the lower limb, especially in the femur, and may be corrected by simple osteotomy. For large bones like the femur and tibia I prefer cuneiform osteotomy, as removal of a wedge yields more accurate apposition of the fragments and lessens the risk of subsequent displacement. If possible, the bone should always be divided just above or below the deformity and not through the line of original fracture; the latter may harbour latent sepsis and the bone is usually sclerotic, so that union may prove unsatisfactory. Occasionally the bone may be secured after operation by the use of pegs or a plate and screws, but this is usually unnecessary and undesirable. After operation the limb is fixed in a suitable position until sound union has occurred, and for this purpose in the lower limb I generally employ plaster-of-Paris. In civil practice angulation is frequently seen in cases of coxa vara following fractures of the femoral neck where the primary deformity has not been rectified by fixing the limb in extreme abduction. Unreduced Colles's fractures are also far too common.

Rotary displacement not uncommonly accompanies angular deformity in the femur and should then be corrected at the same time; rotation alone rarely requires correction in the lower limb. In the upper limb the most common and serious cases of rotary mal-union are found in the radius, the upper fragment being supinated while the lower is pronated. Uncomplicated cases of this deformity may be readily corrected by linear osteotomy of the radius above the insertion of the pronator radii teres and fixing the forearm in full supination, but it is frequently accompanied by angular displacement of the radial fragments towards the ulna which renders the case more difficult and necessitates further treatment.

Another example of rotary mal-union is furnished by a shoulder-joint which has ankylosed in a position of extreme external rotation. I have seen several such cases, following compound injuries of the upper end of the humerus, where the limb has been inappropriately fixed in a straight Thomas's splint. This condition may be satisfactorily treated by linear osteotomy of the humerus below the deltoid insertion.

Overlapping of the fragments constitutes a serious type of mal-union in a number of cases. In the lower limb it is a common deformity of the femur and may be associated with angular or rotary displacements. Slight degrees of shortening are readily counterbalanced by non-operative means, and in gross cases the accompanying contractures of the muscles will contra-indicate operation when the fracture is of long standing. Consequently it is of the utmost importance to restore full length to the bone during early treatment, and once the fracture is consolidated overlapping mal-union should not be disturbed. In the upper limb shortening is of little consequence and never requires operative intervention. Cross union or synostosis of the radial and ulnar shafts accounts for many cases of mal-union in the forearm. The condition is generally considered unfavourable but excellent results may be obtained provided the normal curvature of the radius has been preserved. After thorough removal of the bony bridge a fatty-fascial flap from the thigh is inserted between the bones, the flap is folded on itself so that the fascia lies in apposition with the bone on either side, and is then lightly sutured in place. When associated with angular or rotary mal-union of the radius cross union is less satisfactory and will require other methods of treatment.

Fractures of the articular ends, especially comminuted fractures, are frequently followed by mal-union. Apart from complete disorganisation of the joints in these cases, irregular or excessive callus or displaced comminuted fragments may interfere with joint function. Where the obstruction is extra-articular the condition can usually be remedied easily, but intra-articular cases are not favourable, though occasional successes may be achieved. Ankylosis of the superior and inferior radio-ulnar joints may be treated by excision of the heads of the radius and ulna respectively.

Non-Union.

In dealing with ununited fractures the first question to be decided is whether the condition present is one of delayed union or of true non-union. "Ununited fracture," says Jones,[4] "is often the result of surgical impatience," and "non-union would rarely occur if delayed union received proper attention." For delayed union operative treatment is unnecessary and the presence of non-union is to be determined by X ray examination. By this means atrophic and sclerotic types may be recognised, and when such changes are present in the bone non-union can only be remedied by operative measures.

BONE GRAFTING.

Although it is now more than a century since bone grafting was first successfully employed in surgery, its present popularity is due chiefly to the work of Albee, whose technical improvements have rendered accurate work possible and have greatly increased the scope of the method. It is, moreover, the only method available in dealing with cases in which a gap exists between the fragments if the original length of the bone is to be preserved, and it has therefore had a wide field of application in gunshot fractures, where loss of substance is a common feature.

In spite of the vast amount of work accomplished differences of opinion still exist on technical points.

but certain fundamental principles may be regarded as settled :—

1. The views of Macewen [5] on bone growth are generally accepted. He maintained that the periosteum was only a limiting vascular membrane without bone-forming properties and that osteogenesis was a function solely of the bone cell or osteoblast. These cells are present in greatest numbers beneath the periosteum and on the deep surface of the compact bone, and it is in these regions that bone growth and repair are most active.

2. All observers agree that living autogenous grafts are superior to any others.

3. Grafts should consist of the three elements—periosteum, compact bone, and medulla. The periosteum acts as a vascularising membrane and protects the underlying osteoblasts from injury ; the compact bone gives the graft mechanical strength but is almost devoid of osteogenetic power ; the endosteum is rapidly vascularised and takes an active share in osteogenesis.

4. Such grafts when contacted with living bone possess osteogenetic and osteoconductive properties ; the more favourable the conditions the more active will osteogenesis be. It is true that Murphy,[6] and more recently Gallie and Robertson,[7] denied osteogenetic properties and maintained that a graft always dies and acts only as a scaffolding, the bony tissue being gradually absorbed and replaced pari passu by new bone laid down by osteoblasts which invade the graft from the neighbouring host bone. But the evidence in favour of osteogenesis is strongly against the acceptance of this view.

5. Living autogenous bone grafts are capable of resisting *mild* degrees of infection.

6. Success in grafting is largely dependent on accurate coaptation, wide contact, and firm fixation between graft and recipient bone.

7. The growth of a graft is determined in accordance with Wolff's law, which states that changes in the form, position, or function of a bone are followed by corresponding changes in structure. As Murphy says, "The growth of a bone depends on the need for it."

While the value of bone grafting has been fully established it is acknowledged by all that failures have been common. In part these have been due to technical errors, but many of the cases are exceedingly difficult, and dense scar-tissue, muscular contractures, mal-alignment of the fragments, and latent sepsis are local conditions which may render success well-nigh impossible. For this reason a two-stage operation is often necessary. The first stage consists in excision of scar-tissue, freshening the ends of the bones, and correction of deformities, and is followed by a period of suitable splinting and massage. These measures greatly facilitate subsequent grafting and also provide a useful test for the presence of latent sepsis. If no "flare up" occurs grafting may be performed a few weeks later, but if suppuration has followed further operation should be postponed for a period of at least six months. Infection in grafting usually, though not invariably, spells failure, and no efforts should be spared to avoid it.

Two chief types of bone grafts have been employed : *Intramedullary* grafts, the ends of which are inserted into the medullary cavity of the fragments ; and *cortical* grafts, which are applied in such manner that corresponding layers of graft and host are in contact —periosteum with periosteum, cortex with cortex, and endosteum with endosteum. Intramedullary or "peg" grafts are attractive and possess certain advantages. They maintain accurate alignment of the fragments and require no additional means of fixation, but otherwise they are less satisfactory. They usually possess feeble osteogenetic power and many failures occur, either by lack of union between graft and host or by fracture or absorption of the graft which occurs frequently at the line of contact with one of the fragments. Failures are particularly common in the shafts of the radius and ulna where the medullary cavity is so small that it admits only a slender peg of compact bone almost devoid of osteogenetic properties. The mechanical advantages of the method, however, outweigh these objections in some cases, especially when dealing with a short fragment near the articular end of a bone.

In my experience better results are obtained by the use of cortical grafts, of which *sliding*, *inlay*, and *lateral* grafts are varieties. In suitable cases a massive lateral graft is, perhaps, the most satisfactory of all methods. The fractured ends are freshened laterally by longitudinal division, removing from one-third to one-half the thickness of each, so that the medullary canal is laid widely open and a large cortical graft is then applied. The graft is taken from the tibia, or in some cases it may be obtained conveniently from one of the fragments as a "sliding lateral" graft.

The grafts are usually fixed by means of stout catgut, kangaroo tendon, or silk. Wire sutures or ligatures may also be employed, but it has been my experience that in cases where stress is so great that fixation is difficult the means used is of little consequence, and failure generally follows by fracture or absorption of the graft. Grafts are most readily cut and the bones prepared by means of an Albee's motor saw. Theoretical objections to this method are not supported by practical experience, and by its use much time is saved and more accurate work is possible. Secure post-operative fixation is essential after bone grafting and is usually most satisfactorily obtained by means of plaster-of-Paris. Although the "taking" of a graft is probably determined within a few days, absolute fixation should be maintained for at least six weeks. After this period gentle massage and regulated movements of the muscles stimulate further osteogenesis and strengthening of the graft.

In simple fractures the results obtained by grafting are naturally far better than in the case of gunshot injuries and the method has been advocated extensively even for recent cases, but in my opinion bone grafting should find no place in the treatment of recent fractures and should be reserved for cases of non-union.

Overlapping and Impaction.

When no serious disability is entailed by shortening the limb non-union may be treated conveniently by other methods. Such cases will occur in the humerus and forearm, and in the femur or tibia of a patient who has previously suffered amputation of the other leg. For fractures of the shaft shortening by steppage or the "step-cut" operation is the method of choice. The ends of the bone are freshened on opposite sides in an L-shaped manner, and then secured by means of wire sutures. For fractures near the articular ends steppage is unsuitable and shortening by impaction is a better procedure. The ends are freshened transversely, and the narrower fragment is pointed and then impacted into the other. These methods yield excellent results and are generally followed by prompt union. In forearm cases both bones must be shortened together and then secured, but in the leg the fibula may be resected without fixation.

EXCISION.

Certain intra-articular fractures which are followed by non-union are successfully dealt with by excision of the loose fragment. Such cases occur in the shoulder-, elbow-, hip-, and knee-joints, and in these excision will usually be the method of choice.

In treating of fractures from an operative standpoint I trust that I have created no impression of disparagement of conservative methods. These constitute the routine treatment, and experience in recent years has but strengthened their position. Old principles have been justified, though methods and details have been modified and improved in many cases. Operative procedures occupy an important but subordinate place, and are properly employed to remedy the shortcomings and failures of non-operative measures.

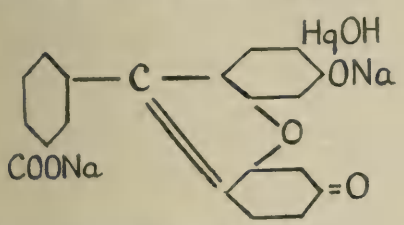
A NEW MERCURIAL FOR THE INTRAVENOUS TREATMENT OF SYPHILIS.

BY W. R. SNODGRASS, B.Sc., M.B., CH.B. GLASG.,

MEDICAL OFFICER IN CHARGE VENEREAL CLINIC, WESTERN INFIRMARY OF GLASGOW; PHYSICIAN TO OUT-PATIENTS, WESTERN INFIRMARY.

White, Hill, Moore, and Young, of Baltimore, have reported favourably on the clinical results of a new mercurial for the intravenous treatment of syphilis.[1] To this mercurial they have given the name "flumerin," and for it they claim a high therapeutic value, especially in experimental infections, along with a low toxicity.

According to Young and his co-workers flumerin is a reddish powder containing 33 per cent. of mercury in the non-ionised form. It is the disodium salt of hydroxymercuri fluorescin. The chemical formula is as follows:—



Flumerin is readily soluble in hot or cold water, and is antiseptic. Freshly-prepared solutions should be used, as after seven to ten days a sediment of metallic mercury appears. In a few instances where two to four day-old solutions were employed, no increase in the toxic effects were seen.

In the cases now under review the drug was used in a 2 per cent. solution, with a dosage ranging from 2 mg. up to 5 mg. per kilogramme of body-weight. In a few cases this dosage was exceeded. For adult males this entails a dosage which varies from 0·2 g. to 0·45 g. in each injection. Injections were usually given at bi-weekly intervals, and the average number of injections was ten. This corresponds approximately with the original method of administration. As a result of treating 25 cases of syphilis, certain definite observations have been made which would appear to justify the publication of a clinical note, and to encourage the further employment of the drug. Eight cases of secondary and 17 of tertiary syphilis were treated. The most interesting results

were obtained from those treated while in the secondary stage of infection, and these are considered firstly from the point of view of cure, clinical and serological, and secondly with reference to the toxic effect of the drug. Table I. summarises the results in the secondary cases.

[1] Jour. Amer. Med. Assoc., 1922, lxxix., 877.

All the cases shown in Table I. before treatment presented gross secondary lesions. In all the Wassermann reaction of the blood (W.R.) was positive, and in seven *Spirochæta pallida* was found. The most satisfactory result was the rapid disappearance of the clinical manifestations. In one case condylomata disappeared in seven days; in another mucous patches of the throat healed in seven days. In all but one case all staining from the various forms of rash present had disappeared before the eighth injection. Adenitis was the most persistent feature, but it too had yielded, with one exception, by the fifth week. The most disturbing clinical finding was the undoubted relapse of two cases while still under treatment and when apparently clinically cured. Case 1 showed a reappearance of condylomata after the twelfth injection of flumerin, although the original condylomata had healed in one week. No spirochætes were found in the relapsed lesions. In Case 2 a hard indurated sore appeared at a fresh site, and numerous spirochætes were obtained from it.

Only in three cases did the W.R. become negative, and in one of these, Case 3, the cerebro-spinal fluid showed a positive reaction. There were no nervous symptoms in this case. The cerebro-spinal fluid was not examined before treatment was started.

The changes in the W.R. do not compare unfavourably with those following the use of any other mercurial used over a similar period.

In order to amplify the presentation of the results of treatment, two cases are quoted in detail—the most favourable and the least so.

CASE 5.—Male, aged 31. Clinical examination on first appearance showed a healed chancre on right side of prepuce with considerable induration. A copious large papulo-squamous rash, with a few follicular spots, present over trunk, limbs, and forehead. A small mucous patch noted at the right angle of the mouth. Generalised adenitis present. W.R. positive. Injections were given at weekly intervals with the results noted in Table II.

TABLE II.

mucous patches over the scrotum and on the left side of the throat were seen. There were brown pigmented spots at the

flexures of groin and axilla. Florid anal condylomata were present. There was a marked general adenitis. W.R. positive. Spirochætes were found in the condylomata and mucous patches. Injections were given at variable intervals with results as shown in Table III.

On July 3rd, 1923, patient showed relapse of condylomata and adenitis. There were no spirochætes found. W.R. positive. There was an early gingivitis. Intravenous arsenical therapy was commenced with good results, both clinically and serologically.

Toxic Effects of Flumerin.

The toxic effects of the drug will be considered in conjunction with the series of tertiary cases. These numbered 17, and included subcutaneous gummata, skin lesions, ulcerative gummata, and Wassermann-fast patients with latent disease. All lesions disappeared under treatment with flumerin alone. The skin lesions were usually healed after about eight injections, though pigmentation persisted. The subcutaneous gummata and ulcerative lesions were slower in disappearing, ten injections being usually required. No clinical relapses occurred.

These results are good. Flumerin seems much more potent in its clinical effects than other mercurials. All workers must be familiar with the persistence of gummatous lesions under mercurial treatment alone. In one case of leukoplakia of the tongue treatment was interrupted after the tenth injection of flumerin on account of the development of a papilloma on the tongue. Histological examination showed this to be a simple tumour. The leukoplakia was not improved.

In no case was the W.R. changed from positive to negative. This is not surprising in view of the duration of treatment.

The toxic effects may now be considered. At the site of injection no ill-effect was seen. Toleration was complete in six out of the 25 cases. In five cases the complications which ensued were sufficiently severe to compel a change of treatment. In the remaining 14 cases marked reactions occurred, but it was possible to continue treatment with flumerin by carefully adjusting the dosage. The majority showed an improvement in toleration even of large injections of the drug. Sickness, headache, abdominal cramp, and diarrhœa were the chief complaints. Sickness was often immediate, and had some relation to the previous ingestion of food. A two-hours' preliminary fast is a necessity. At times vomiting followed, and lasted intermittently for 24 or, rarely, 48 hours. Headache and malaise were usually not marked. Cramp in the epigastrium and hypogastrium was the most striking complaint, and was obviously related to the excretion of the drug. After two out of a total of 280 injections it assumed alarming proportions. Diarrhœa for 24 or 48 hours was fairly frequent. The severer cases were accompanied by colic, and in three instances there was said to be the passage of blood. Pain in the mouth was occasionally mentioned. In three cases a mild gingivitis or stomatitis developed. The original workers record a number of cases of albuminuria. In the 25 now under review, renal efficiency was apparently fully maintained, and no albuminuria was found. One case calls for special notice.

A female, aged 31, with latent tertiary syphilis was given two injections of 0·20 g. and 0·25 g. one week intervening. These doses were well tolerated. She was then given 0·30 g. three days after the second injection. In eight hours she was seriously ill with colic, bloody diarrhœa, headache, and collapse. She recovered in four days under stimulant and eliminant treatment. Very small doses of flumerin were given again, but a threatened return of the symptoms compelled a change of treatment.

The age, sex, and general physical condition of the patients apparently gave no clue to their probable toleration of flumerin. The only rule for treatment is caution with the initial dose, and careful observation of its results. These toxic manifestations indicate a lesser or greater degree of acute mercurialism, and it is noteworthy therefore that no alteration in the output or character of the urine was seen. The drug is rapidly excreted, and it is considered that chronic mercurialism due to storage of the drug should be rare.

More perhaps has been made of the toxic effects than is justifiable. The vast majority of the injections were well borne, and the side-effects are no worse than those following any other intravenous mercurial. As the drug is a new one, each weak point in its use was minutely recorded, and the majority of the symptoms were elicited only after questioning the patient. Care is required in the use of flumerin, but it is not contra-indicated on account of its toxicity. Although the number of cases treated is small, certain definite observations have been made, and as further use of flumerin will be combined appropriately with arsenic or iodide—this being also the experience of the original workers—the following conclusions are suggested.

1. Gross secondary lesions show material alteration in the direction of healing within one week as a result of the administration of flumerin alone. No other mercurial preparation would appear to produce marked changes so rapidly.

2. The action is not lasting. Relapses in secondary cases may occur within a relatively short time or even while treatment by flumerin is being continued.

3. A positive W.R. is usually not altered to a negative one. In this respect flumerin does not compare unfavourably with an equivalent use of other mercurials given without salvarsan preparations.

4. Tertiary cases which present definite lesions show rapid clinical improvement with flumerin alone. The rapidity appears much greater than that produced by other mercurials, but less than by combined treatment by mercury and iodide. No effect upon the W.R. is noted. This is not significant in view of the duration of treatment.

5. Marked toxic effects of the nature of acute mercurialism were occasionally seen. Conversely cases of great toleration were noted. The reason for this is apparently not related to the patient's general physical condition.

6. Extended trial of flumerin should be made on account of its rapid antisyphilitic effect. This rapidity is its outstanding property. At the same time, even the restricted observations here recorded indicate clearly that the drug should be used along with salvarsan preparations or iodides, as the case demands.

The venereal diseases department is much indebted to Dr. H. H. Young, who placed at Prof. C. H. Browning's disposal a quantity of flumerin sufficient to treat 25 cases.

THE INCIDENCE OF KETOSIS IN CASUALTY PRACTICE.

BY O. W. ROBERTS, M.B., B.S. LOND.,
SENIOR CASUALTY OFFICER, KING'S COLLEGE HOSPITAL, LONDON.

WITH a view to tracing, if possible, the incidence of ketosis in casualty cases, an investigation has been made of a number of patients of all ages admitted to the casualty ward of the above hospital during a period of ten months. No case was classed as ketosis which did not give positive chemical results on examination of the urine. The tests employed were Rothera's tests for acetone, and the ferric chloride test for aceto-acetic acid; while in doubtful cases in which salicylates had been given for the relief of pain Gunning's iodoform test was employed. (The tests are described at the end of the paper.)

In 393 cases examined only 11 had received general anæsthetics before examination for acetone; all of Class 1 and Class 3*b* were quite healthy until the time of admission, and about 30 per cent. of the other cases were similarly in perfect health until the day previous to their admission. The 36 cases not included in the above table consist of tumours removed and of adult circumcisions performed under local anæsthesia, and a number of cases admitted for observation and diagnosis, mostly of a medical

rather than a surgical character. None of these developed ketonuria.

Examination of the table shows that Class 2 (irritation of mucous membrane) has the largest percentage of cases of ketosis. The respiratory and alimentary systems are grouped together in this table because clinically, especially in the younger cases, acute irritation of one system was often associated with evidence of involvement of the other—e.g., an acute tonsillitis was found to be associated with pharyngitis, bronchitis, bronchiolitis, or gastritis.

Table of Cases Examined.

Class.	10 years and under.	10–20 years.	Over 20 years.	Total.	Percentages.

Total number of cases examined 393
Number of cases under 10 years.. 150
Total number of ketosis .. .. .. 168 = 43 %
Number of ketosis patients under 10 years .. .. .. 99 = 66 %

Note.—Seven of the intestinal cases under 10 years of age were too young for a specimen of urine to be obtained and are counted as negatives.

Sore Throat.

A large number of the cases brought to the casualty department for treatment for "sore throat" were found to have ketosis, in these there was a history of acute onset of sore throat and headache followed by drowsiness; vomiting was not usual; the mother in some cases had noticed a "sweetish smell" in the breath, and the urine showed the presence of acetone bodies. Only those cases, with five exceptions, which were admitted to the ward for treatment are included in the above table, hence the proportion of cases of this class treated as out-patients and who developed ketosis is not known. Most of the cases under ten years of age who were admitted had bronchial and pulmonary complications. One interesting case of this group was that of a woman, aged 35, admitted suffering from coma of unknown origin, and with a temperature of 102° F. Her urine was found to contain a large quantity of acetone bodies, but no other abnormal substance; sodium bicarbonate was given rectally and subcutaneously. The following day she was much better, and stated that the day before her illness she had a "very bad sore throat"; on examination her tonsils and pharyngeal mucous membrane were found to be very inflamed.

In the cases classed above in Class 2, group (*a*) (irritation of respiratory tract), it was found that the more severe the inflammation and the more rapid its onset the more marked was the ketosis. Also the younger the child the more did it appear to suffer from ketosis, as shown by the marked improvement clinically after alkali treatment, although the respiratory condition showed little or no improvement. This group would naturally include cases of tonsillectomy and adenoid curettage, but as such cases are subjected to general anæsthesia they have not been included in this series.

Irritation of Gastro-intestinal Tract.

Cases of irritation of the gastro-intestinal tract were found to fall into two sub-groups. The first sub-group (*a*) consists of those cases in which the irritation was present primarily in the lumen of the bowel, the initial picture being one of acute gastritis or gastro-enteritis. There was in most of these a definite history of dietetic indiscretion, or of the swallowing of an irritant poison, together with a gradual increase of abdominal discomfort followed by nausea and vomiting or diarrhœa. The patients were brought to hospital on account of the abdominal condition and of drowsiness, and all showed marked improvement on being treated with alkalis. One interesting case was watched from the commencement: A boy, aged 2½ years, had swallowed an unknown quantity of oil of eucalyptus; he was brought to hospital about half an hour afterwards, on the way he had vomited; his condition on arrival suggested severe shock. He was given an emetic and treatment for shock adopted. The drowsiness increased, and a specimen of urine obtained about five hours after admission showed the presence of acetone bodies. The child became more and more drowsy, but showed marked improvement upon the administration of alkalis. There was no vomiting apart from that occurring immediately after the drug was swallowed and that which resulted from the administration of the emetic; but there was marked tenderness over the epigastrium, and a mild diarrhœa commenced a few hours later. The ketosis lasted for two days after his recovery clinically.

The second sub-group (*b*) consists of cases in which the site of irritation was unknown; in some the irritation was probably due to abnormal contraction of the intestinal muscles. The initial picture in these cases was chiefly that of an "acute abdomen" accompanied by collapse, the patient having been quite well until the onset of severe abdominal pain. A typical case of this sub-group is the following. A girl, aged 11 years, was seized with an attack of severe abdominal pain while drilling at school; the child "doubled up" and "fainted," but did not vomit. On admission the temperature was 100° F., pulse 110, facies anxious and pale, pupils dilated, while she lay limply on the couch and looked very ill. The abdomen showed very little movement on respiration; there was no rigidity, but there was tenderness on the right side, particularly over the liver; the breath smelt strongly of acetone, and the urine contained acetone bodies. A few hours later ketosis was well marked, and alkali treatment cleared up the symptoms, while no further abdominal symptoms developed. Some patients of this group who had not vomited at the onset of the symptoms started vomiting as the ketosis developed; the vomiting became worse, and was accompanied by headache and marked drowsiness.

Trauma.

The cases included in Class 1 (trauma) have the next highest incidence of ketosis. These cases are divided into two groups, because in cases of head injury and concussion the symptoms of severe ketosis may lead to difficulty in diagnosing intracranial complications. The usual picture of cases of group (*a*) was the following. A child, 8 years old, was brought into hospital, very irritable, with bleeding from the nose or ear; there was a history of a head injury and unconsciousness lasting for some minutes. About five hours after admission the breath was noticed to smell of acetone and a specimen of urine obtained at this time showed traces of acetone bodies; a little later the child became very drowsy and started vomiting, and the acetone excreted increased in quantity. The child lay very limply in bed, with the face pale, and respiration chiefly of the costal type. When roused he was very irritable; vomiting was forcible, and was more marked when any attempt to swallow fluid was made. Treatment with alkali diminished and eventually cleared up the symptoms.

Several cases have been carefully watched from the time of admission, and in those where vomiting had not occurred at or soon after the time of the injury it did not commence until ketosis was definitely established. This in most children occurred about five hours after the injury, acetone being then easily detected in the breath. The vomiting and ketosis in mild cases pass off in two or three days without any treatment; but in cases of severe concussion the ketosis increases, the vomiting becomes more severe, and the child suffers from loss of fluid and exhaustion, unless alkali treatment is adopted. The vomiting and drowsiness occurring some hours after the head injury in children under 10 years of age appears to be due, in a large number of cases, more to ketosis than to any actual brain lesion; and the change in the condition of the child after alkali treatment is sometimes very surprising.

The following case is worthy of note. A boy, aged 2 years, was sent to the hospital in an apparently moribund condition as a case of possible intestinal obstruction; there was a history of severe vomiting for three days. The smell of acetone was well marked in the room in which the child was waiting; the child looked very ill, with the typical picture of severe acute ketosis. On physical examination there was nothing to account for the vomiting. The parents were carefully questioned, and stated that before the vomiting started the child had fallen from a chair on to its head and had been "very drowsy" for some time afterwards. Eight ounces of a mixture of isotonic glucose solution and potassium citrate were given subcutaneously, and sodium bicarbonate was administered by the mouth. The following morning the child was well on the path to recovery.

The cases of extracranial head injury which I examined did not develop ketosis; while in the cases of children under 10 years in which there was undoubted brain injury as evidenced by fits or spasticity a severe ketosis developed. It is interesting to note in this connexion that a large number of children develop severe ketosis after mastoid operations. Cases in group (*b*) (other injuries) include patients run over by vehicles, and work accidents and fractures. Three cases of traumatic pneumothorax in children under 10 years developed a severe ketosis within a few hours of their admission, and the relief of symptoms after alkali treatment was remarkable, the respiration becoming easier and the colour and general condition much better. Of the ketosis patients over 20 years of age, six were cases of chest injury.

Toxæmia.

The third class of case is divided into two groups: (*a*) cases of suppuration, (*b*) cases of burns and scalds. A large number of the first group of cases were of gradual onset. There was usually a history of malaise lasting for some days, a small scratch or injury which gradually formed a septic focus with local tissue destruction, and possibly a mild septicæmia. Only those cases which had a high temperature and severe toxic symptoms developed ketosis. The other cases were acute inflammatory conditions, with rapidly progressing cellulitis, lymphangitis, and marked severe general symptoms, while the onset was usually relatively very sudden. This condition occurred mainly in patients who, prior to the skin wound, were in apparently good health. All cases of this type examined showed a marked ketosis on admission.

The second group of this class consists of cases of burns and scalds. All those which developed a marked ketosis had also respiratory complications; cases which did not develop respiratory complications exhibited a mild ketosis or no evidence of acetone in the urine, although in a few cases the initial shock was severe. The ketosis cases under 10 years of age were kept under observation for some time after their discharge from hospital, and it was found that those patients who developed marked ketosis with well pronounced general symptoms suffered from general debility for a considerable time afterwards. In these cases the mother stated that the child was "fretty" and took no interest in life or in food, and the child appeared pale and listless for some weeks after discharge. Cases treated early with alkalies made a more rapid recovery.

The treatment adopted in cases of ketosis consisted in the administration of a purgative and of alkalies. An initial dose of 20 gr. sodium bicarbonate to children, 30 to 60 gr. to older patients, was given and repeated every two or four hours according to the condition of the patient. In most of the severe cases there was a well-marked improvement after the third dose. The patient was encouraged to drink plenty of fluids with glucose or lemon-juice. Prolonged administration of sodium bicarbonate was found to irritate the stomach in some instances, and citrate of potassium or of sodium, 20 to 30 gr., was used instead. In cases with severe vomiting 30 gr. sodium bicarbonate was given subcutaneously in a 5 per cent. solution of glucose or of citrate of sodium as well as by mouth. The doses were decreased as soon as the acute symptoms had passed off, and the patient was encouraged to eat carbohydrate and fruits. The urine in severe cases was found to contain acetone bodies for some days after the clinical condition had improved.

Suggested Conclusions.

The total number of cases examined is too small to allow any definite conclusions to be drawn; but the following are suggested. Cases of trauma, particularly head injuries, cases of acute irritation of the intestinal or respiratory mucous membrane, and cases of acute suppuration may be complicated by the onset of an acute severe ketosis; the younger the patient the greater is the possibility of this complication. This severe ketosis may aggravate and mask the symptoms due to the primary condition. The central nervous system, having no protection in itself against ketosis or acidæmia, suffers most, as is evidenced by the drowsiness, irritability, and headache.

Ketosis, if untreated, may lead to severe vomiting, may interfere with the patient's recovery, and may prolong the convalescence. In any case our knowledge of the central nervous system is so incomplete that the result of a temporary damage to the nerve cells by ketosis cannot be estimated; and the general debility, listlessness, and dread of mental strain seen in concussion cases of school age for months after the injury may be due to the results of ketosis rather than to a possible physical trauma at the time of injury.

Treatment consists in the administration of alkalies and aperients. In children prophylactic treatment with alkalies in cases of acute trauma and inflammatory conditions would diminish the occurrence of acute ketosis and would not cause any harm to the patient.

Tests for Acetone Bodies.

1. *Rothera's Test* (Modified).—Add ½ in. of a mixture of powdered crystals of ammonium sulphate, 20 parts, and sodium nitroprusside, 1 part, to a test-tube half full of urine, then add ½ in. of strong ammonia solution; shake well and allow to stand. A permanganate colour develops if acetone bodies are present.

2. *Ferric Chloride Test.*—Add liq. ferri perchlor. solution, drop by drop, to a test-tube half full of urine until no further precipitate of ferric phosphate is formed; further addition of the solution gives a Bordeaux-red colour if aceto-acetic acid or salicylates are present.

3. *Gunning's Iodoform Test.*—Add an alcoholic solution of iodine and a little strong ammonia to a test-tube half full of urine; a mixed precipitate of iodoform and black nitrogen iodide is formed if acetone is present; the black precipitate disappears, leaving the yellow precipitate of iodoform.

OBSERVATIONS ON CUTANEOUS HYPERÆSTHESIA IN ACUTE ABDOMINAL DISEASE.

BY ZACHARY COPE, M.D., M.S. LOND., F.R.C.S. ENG.,

SURGEON TO OUT-PATIENTS, ST. MARY'S HOSPITAL; SENIOR SURGEON, BOLINGBROKE HOSPITAL.

IT has long been known that acute abdominal disease may be accompanied by increased cutaneous sensibility, but the almost complete silence of the text-books on the subject is sufficient evidence that the value of such hyperæsthesia is either not recognised or is under-estimated. When reference is made to the subject the information afforded is often erroneous. For example, Blos[1] writes:—

When the pain triad has been present (skin-hyperæsthesia muscular defence, painful McBurney's spot) we have always found peritoneal suppuration. Especially skin-hyperæsthesia is of the greatest significance.

A very short series of observations would serve to show any accurate observer that cutaneous hyperæsthesia does not necessarily indicate suppuration. The attitude of most surgeons to the subject appears to be that of scepticism as to its value in diagnosis, and doubt as to any certain conclusions which may be drawn from its presence.

Historical.

More than 20 years ago Head [2] noted cutaneous tenderness over the right tenth dorsal segmental area in a case of strangulated femoral hernia containing small gut, and from many observations he came to the conclusion that the intestines might cause referred pain in the distribution of the tenth, eleventh, and twelfth dorsal segmental nerves. The first surgical observer who attempted to systematise our knowledge on the subject was Sherren,[3] whose classical paper on hyperalgesia in acute appendicitis has been grievously overlooked by the profession. Sherren investigated 124 cases of acute appendicitis and detected increase of cutaneous sensibility in 40 cases. He concluded that in appendicitis the hyperalgesia usually occupied the eleventh dorsal segmental area, sometimes encroaching on the tenth or twelfth dorsal areas. I will quote his words:—

In appendicitis cutaneous hyperalgesia varies from a complete band extending on the right side from the middle line below the umbilicus in front to the lumbar spines behind, down to a small circular spot a little above the middle point between the umbilicus and the anterior superior spine. This band corresponds to the eleventh dorsal area of Head. Very often the tenderness extends somewhat into the tenth dorsal area also, and occasionally but not often into the twelfth dorsal area, sending a tongue-shaped process over the gluteal region. The width of the band is in the adult about 3 inches. The normal area is on the right side of the abdomen and is of a triangular shape. Its lower boundary reaches almost to Poupart's ligament, its inner almost to the middle line, and its apex is a little outside the anterior superior spine, sometimes extending to the mid-axillary line.

Cutaneous tenderness in appendicitis is occasionally bilateral. I have never yet seen a case in which the hyperalgesia was present on the left side alone. In the gangrenous type of the disease no such tenderness can be discovered when the patient comes under observation. If a patient is progressing favourably the hyperalgesia clears as the symptoms of the disease improve, rarely persisting in the first attack after the sixth or seventh day.

Mr. Sherren believed that distension of the appendix was the main cause of the hyperalgesia, and concluded that sudden loss of the symptom, provided that the other symptoms remained, indicated perforation of the appendix. In cases of appendicular abscess he found only 10 per cent. exhibited hyperalgesia. His observations led him to conclude that increased cutaneous sensibility was not found in other diseases of the intestines. Further observations on the same lines were carried out by H. Robinson,[4] who investigated 200 cases of acute abdominal disease. In 123 cases of acute appendicitis Robinson found hyperalgesia in 26 cases. The areas involved corresponded for the most part to those described by Sherren, but Robinson differed from Sherren in concluding that—

(*a*) Other diseases can give rise to hypersensitive areas somewhat similar to those caused by appendicitis.

(*b*) In some cases at least tension within the appendix cannot be the exciting cause.

(*c*) The symptom is present in cases of appendicular abscess in only a slightly lower percentage of cases than those cases without abscess.

Robinson found cutaneous abdominal hyperæsthesia in one case of perforated ulcer, in three cases of gall-stones and cholecystitis, in two cases of perimetritis, and in one case of intestinal colic. Since the publication of Robinson's paper little work appears to have been done on the subject, though Ligat [5] published some observations which so far as I am aware have not been confirmed by others. My own conclusions are based on nearly 300 cases, and they confirm, modify, and extend the observations of Sherren and Robinson.

Methods of Testing for Hyperæsthesia.

There are two simple methods of testing for hyperæsthesia—the pin-stroke and the light pinch. The pin-stroke consists in drawing the point of a pin lightly across the surface of the skin of the abdomen from the costal margin down to Poupart's ligament. This should be done on both sides in several places working from the mid-line outwards. The patient is asked to indicate if at any part of the stroke the sensation varies, or feels sharper, or causes pain. To find the exact lower limit of any area of increased sensibility it is wise to draw the pin from below upward, for it is easier for the patient to feel an increase than a decrease of sensibility. One is occasionally astonished to find that there is a definite hyperæsthesia when the pin is drawn from above downwards, but none detectable when the stroke is in the reverse direction. To discriminate between the sensitiveness of the two sides of the body it is necessary to draw the pin lightly across from one to the other side of the mid-line.

Several small details must be attended to if an accurate result is to be obtained by the pin-stroke. The point of the pin must be held at the same angle to the skin all through the stroke. It is very easy (especially if the clothes or bed-clothes are not well out of the way) to finish the stroke on the lower abdomen with the pin at an angle approaching the vertical instead of the suitable angle of about 30°. This would cause a natural increase in the patient's sensation. In one case showing hyperæsthesia when I had been careful to keep the pin at the same inclination to the skin the patient remarked when the hypersensitive area was reached that it felt as if the pin had been raised more to the vertical.

At the first trial the patient may not say quickly enough when the increase in sensation occurs. If therefore any positive result be obtained it is wise to perform the test again much more slowly so as to obtain the exact limit of the affected area. Care must also be taken that the pin used has not a bent end which may scratch and vitiate the test. (Any light object could be used for the test, but a pin is the most handy object and the point affords an extremely delicate indication of sensibility.) The amount of pressure used should be very slight and uniform all through the stroke. In patients with very brisk abdominal reflexes the pin should be specially steadied by the forefinger. The sensation caused by the stroke should only just be perceptible to the patient on normal areas.

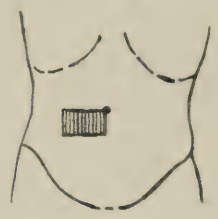
The pinch test needs little explanation. Corresponding portions of skin on each side of the middle line are gently pinched between finger and thumb and the patient asked if there be any difference in the sensation. Different areas on the same side of the body are similarly compared and any difference noted. As a rule, the abnormal areas found by one of these tests will tally with those found by the other, but occasionally one method succeeds where the other fails, or the areas affected may not be equal in extent.

In two cases I found hyperæsthesia to pinch and none to pin-stroke, whilst in two others the area hypersensitive to pin-stroke was considerably less than that due to pinch.

The cases I have investigated form a consecutive series seen during the course of 30 months. I have excluded from the list almost all the strangulated

FIG. 1.

FIG. 2.



Hyperæsthetic areas caused by appendicitis.

external herniæ since I have found practically all these cases negative. All the cases quoted were examined by me and (with very few exceptions) all the operations were undertaken by me.

Frequency of Occurrence of Hyperæsthesia.

Before estimating the frequency of occurrence of increased cutaneous sensibility it is necessary to distinguish between the terms hyperalgesia and hyperæsthesia. By hyperalgesia should be understood that state in which pain is felt on stroking the affected area lightly, whilst by hyperæsthesia one indicates a state of increased sensitiveness not necessarily causing pain on touching gently. It suffices for the patient to say that he feels a little more sharply over the affected area. Sherren detected hyperalgesia in only 32·3 per cent., whilst Robinson found hyperalgesia in only 21 per cent. of his cases of appendicitis. In my own series I found some area of hyperæsthesia in 59 per cent. of cases of appendicitis, and in 47 per cent. of all cases coming under the general category of the acute abdomen. Robinson only found hyperalgesia in about 16 per cent. of all acute abdominal cases. There is thus a great discrepancy between the figures of former observers and my own. The only feasible explanation of this is that both Sherren and Robinson took the elicitation of pain as the criterion of increased sensibility, whilst I searched for any slight exaltation of sensitiveness. I tell the patient to say at once if there is any increase of sharpness, whereas Robinson writes :—

> It is advisable to start at some distance from the usual seats of tenderness and thence to advance gradually towards the appendix region until the patient complains of a sensation of pain.

It is clear that the value of the test is greatly enhanced by taking a criterion which gives a positive result in so much greater a proportion of cases—provided, of course, that the criterion is of value. This I hope to show in this communication.

What Cases of Acute Abdominal Disease may present Cutaneous Hyperæsthesia as a Symptom?—I have found hyperæsthesia in a varying proportion of cases of acute appendicitis, perforated gastric or duodenal ulcer, cholecystitis and gall-stones, primary peritonitis, salpingitis with pelvic peritonitis, acute tuberculous peritonitis, ovarian cyst with twisted pedicle, renal colic, pyelitis, abscess of the spermatic cord, intestinal obstruction, and acute dysentery. I propose to consider first the types of hyperæsthesia associated with each of these conditions, and then to discuss certain problems which arise from the facts set forth.

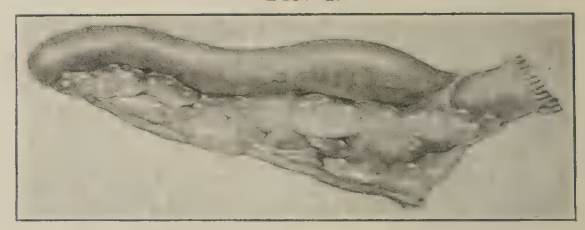
Acute Appendicitis.

Hyperæsthesia of greater or less extent was found in over 59 per cent. of cases of acute appendicitis (110 out of 185). Though perhaps more common with an unperforated distended appendix it was quite frequently found with a gangrenous or ruptured appendix or an undistended unperforated viscus. Abscesses in the first few days of their formation were also frequently accompanied by hyperæsthesia of more limited extent. The position and extent of the hyperæsthesia varied greatly. In nearly all the cases it was limited to the right side of the abdomen, but in eight cases it was bilateral, though not usually so extensive on the left side as on the right. In one case only was the area of increased sensibility confined to the left side. In the great majority of cases the part affected was somewhere within an area bounded below by Poupart's ligament and above by a line drawn outwards horizontally from the umbilicus. In only a very small percentage did the area extend above the level of the umbilicus or below the level of the groin.

FIG. 3.

Hyperæsthetic band corresponding to tenth dorsal segment, caused by appendicitis.

FIG. 4.



Appendix which caused hyperæsthetic band shown in Fig. 3.

Usually only the anterior part of the abdominal wall was involved. When a complete half-girdle band was present it was in the form of a zone 2 inches broad, the upper limit forming a line which extended out from the level of the navel. This corresponds to the area usually looked on as the tenth dorsal segmental area (see Fig. 3).

The so-called appendix-triangle (Sherren) (see Fig. 5 a) was found in about one-fifth of the cases

FIG. 5.

a — Dec. 21st.*
b — Dec. 29th.
c — Dec. 31st.

* Before operation and several days after.

Showing persisting hyperæsthesia after removal of appendix.

showing hyperæsthesia. It was sometimes found with a perforated or gangrenous appendix, but more commonly with an unperforated distended appendix. The typical triangle had as its boundaries the middle line, Poupart's ligament, and a line drawn outwards horizontally or slightly obliquely upwards from the umbilicus. It ended in a blunt angle just above and external to the anterior superior spine. Sometimes there was also a less marked hypersensitive triangle on the left side of the abdomen, and in one case the hypersensitive area was confined to a triangle on the left side. Complete triangles were the exception. In most cases only the lower or medial parts of the area

were hypersensitive. Very seldom, indeed, was the outer portion of the triangle alone affected. When such happened there was usually an abscess close under the affected part of the abdominal wall. There were many variations in the hypersensitive areas, some of which are here illustrated (see Figs. 1, 2, 3, and 5 a).

Speaking generally, the areas nearly always occupied some part of the region supplied by the tenth, eleventh, and twelfth dorsal segments of the spinal cord. So far as one could ascertain in the 110 cases showing hyperæsthesia, the twelfth segmental area was involved in 66 cases, the eleventh in 62 cases, and the tenth in 56 instances. There were four cases in which the sensitive area spread up to the ninth segmental area, and four cases showing hyperæsthesia in the upper part of the thigh below Poupart, presumably the first lumbar area.

The position of the appendix made no difference to the position or the extent of the hyperæsthesia. Whether the vermiform process was in the pelvis or high up under the liver the superficial tenderness was always in the lower abdomen. As will be noted later, inflammation of the gall-bladder may be accompanied by a band of hyperæsthesia just above the fold of the right groin (twelfth dorsal), but this band seldom invades the eleventh and never the tenth segmental area. The point is useful in diagnosis, as was illustrated in the case (No. 227) of a lad with acute abdominal symptoms and a history suggestive of appendicitis, who presented tenderness on deep pressure only in the right hypochondrium close under the rib margin. There was no tenderness on pressure in the right iliac region, but definite hyperæsthesia over an area just below and to the right of the navel. Diagnosis of appendicitis was confirmed at operation when a perforated appendix was removed from its position high up under the liver in the angle between that viscus and the posterior abdominal wall.

I mentioned above that the hyperæsthesia was seldom found posteriorly. It was demonstrated in that position in but 13 cases. Five of these corresponded to the tenth segment only, two to the eleventh, whilst three extended just above and below the posterior part of the iliac crest. The remainder showed hyperæsthesia extending from the last rib to the iliac crest. I have not yet seen a case of appendicitis presenting hyperæsthesia only posteriorly.

Perforated Gastric and Duodenal Ulcers.

Contrary to what one might expect, the great irritation of the peritoneum consequent on the perforation of a gastric or duodenal ulcer is not usually accompanied by hyperæsthesia of the overlying skin. In a recent series of 19 consecutive cases, I only found six which showed this symptom in any degree. One of these had a simultaneous inflammation of the appendix and should not be included since the iliac triangle of hyperæsthesia had disappeared the day after the removal of the appendix and suture of the duodenal ulcer. The other five cases were as follows:—

CASE 172 showed an area of hyperæsthesia corresponding to the lower and inner part of the right iliac triangle. Operation revealed free bile in the peritoneal cavity and a duodenal ulcer which, though sealed up, had clearly allowed the leakage.

CASE 190, in which there was a large perforation of a duodenal ulcer, showed a broad band of hyperæsthesia above the right Poupart's ligament. Within a week after suture of the ulcer the hyperæsthesia had completely disappeared.

CASE 203 was that of a duodenal ulcer, which leaked into the right subphrenic space. When seen by Dr. W. L. MacCormac soon after the onset of the acute pain there was hyperæsthesia over the whole of the lower costal region on both sides. When I saw the patient four days later there was no hyperæsthesia.

CASE 242 showed a hyperæsthetic band above the right Poupart's ligament. Operation revealed a perforation of the first part of the duodenum.

CASE 277 was that of a perforation into the general peritoneal cavity of an ulcer on the anterior wall of the stomach. Before operation pin-stroke demonstrated a narrow band of hyperæsthesia (above an inch broad) above each Poupart's ligament.

It will be noted that in all but one of these cases the hyperæsthesia was just above Poupart's ligament corresponding to part of the twelfth dorsal segmental area. I have never seen the tenth segmental area affected with a perforated ulcer of the stomach or duodenum. The hyperæsthesia in the case of the acute subphrenic abscess was probably due to direct stimulation of the lower intercostal nerves.

Cholecystitis and Gall-stones.

Amongst the 16 cases of acute disease of the biliary tract which were investigated hyperæsthesia was demonstrated in but six cases. They were as follows:

CASE 153.—A woman, aged 67, with hyperæsthesia on the right side of the abdomen forming a band between two and three inches broad immediately above Poupart's ligament. Operation revealed an acutely inflamed gall-bladder and many gall-stones.

CASE 53.—A woman with right-sided abdominal pain was found to have a broad band of hyperæsthesia above the right Poupart's ligament and crest of the ilium, back as far as the outer border of the erector spinæ. At operation the retro-peritoneal tissues from the gall-bladder down to Poupart's ligament were infiltrated with bile which glittered with cholesterin crystals. No rupture of the gall-bladder was detected. A stone was removed from the gall-bladder, which was drained. This patient died ten days later, but no autopsy was obtained.

CASE 198.—A woman, aged 37, had severe colic, and presented symptoms suggestive of cholecystitis. There was slight hyperæsthesia to pin-stroke over the tenth rib posteriorly. At operation there was a stone impacted in the cystic duct, some cholecystitis but no contiguous peritonitis.

CASE 126.—A woman, aged 58, exhibited a patch of hyperæsthesia (to pinch only) just below and to the right of the umbilicus. At operation an inflamed gall-bladder was found in contact with the parietes immediately under the area indicated.

CASE 256.—A man, aged 43, presented symptoms of acute cholecystitis. He showed an area of hyperæsthesia above and to the right of the navel, corresponding to the anterior part of the ninth dorsal segmental area. At operation the gall-bladder was found very inflamed, and there were patches of gangrene in its walls. There was a stone in the entrance to the cystic duct.

CASE 176 was that of a woman aged 32, who suffered from acute right-sided abdominal pain, and showed a band of hyperæsthesia two inches broad immediately above the outer half of Poupart's ligament and the anterior two inches of the iliac crest. At the operation there was free bile in the peritoneum, and bile infiltration of the posterior parietal peritoneum to the right of the descending portion of the duodenum. There was no ulcer of the duodenum nor perforation of the gall-bladder, and no gall-stones were found.

It will be seen that in gall-bladder disease hyperæsthesia may be detected either in the ninth segmental area, which is the segment usually regarded as the source of the nerve-supply of the viscus, or the twelfth segmental area above Poupart's ligament. The only case in which the tenth segmental area was involved was clearly due to the direct irritation of the parietes by the subjacent inflamed gall-bladder. It is quite conceivable that both the upper and the lower areas might be simultaneously involved in a case, but so far I have never seen such an occurrence. It is worthy of note that in all the cases showing supra-Poupart hyperæsthesia there was right-sided peritonitis spreading down to the iliac fossa. It is reasonable to suggest that such peritonitis may have been the cause of the superficial hyperæsthesia, since the gall-bladder is not directly supplied by any fibres from the last two dorsal segments.

Primary Peritonitis.

By primary peritonitis is meant that form in which there is no sign of extension from a viscus either by perforation or contiguity. In the series of cases examined there was one staphylococcal infection, two cases of acute tuberculous peritonitis, and one case from which no organism was recovered. Each one of these cases showed extensive hyperæsthesia.

CASE 107.—A lad, aged 16, who had had acute abdominal symptoms for six days, presented a tender and rigid lower abdomen, with extensive hyperæsthesia reaching from the mid-line in front to the vertebral spines behind. In front the affected area was limited above by a line drawn obliquely outward and upward from the umbilicus, whilst posteriorly it

reached to the last rib and first lumbar spine. The lower limit was formed by Poupart's ligament and the iliac crest. Operation revealed extensive peritonitis, congested intestines, œdematous parietal peritoneum, flakes of lymph on the intestines, and a collection of fluid in the pelvis. The appendix was not so inflamed as the rest of the intestines. Staphylococci were grown from the peritoneal exudate. The hyperæsthesia gradually disappeared as convalescence proceeded.

CASE 221.—A lad, aged 13, with acute abdominal symptoms presented extensive hyperæsthesia on both sides of the body, limited below by Poupart's ligament and the iliac crest and above by a line drawn out from the navel back to the spine. Operation demonstrated free serous fluid in the peritoneal cavity and an extensive peritonitis. The appendix showed slight catarrhal inflammation and contained some thread-worms, but the inflammation was of too slight a nature to be responsible for the peritoneal condition. No growth was made from the peritoneal effusion.

CASE 137.—Acute tuberculous peritonitis. A lad, aged 13, who suffered from diarrhœa and vague abdominal pains for three days, suddenly developed right iliac pain. Temp., 103° F.; resp., 26 | pulse, 110. There was extensive bilateral hyperæsthesia in front only, extending from an inch or two above the navel down to Poupart's ligament. For an inch or two above Poupart's ligament on the right side a light pin-stroke caused him to catch his breath and cry out with pain—i.e., true hyperalgesia. At the operation acute miliary tuberculosis of the peritoneum was found. The cæcum and end of the ileum were very inflamed, matted together, and adherent to the posterior parietes in the right iliac fossa. The hyperæsthesia gradually disappeared. In a fortnight the formerly hyperalgesic area was still hyperæsthetic, whilst the rest of the area was normal.

CASE 164.—Acute tuberculous peritonitis. A young woman, who gave a history of one week's abdominal pain, presented on examination a tenderness in the right iliac fossa and hyperæsthesia reaching from just above the umbilicus to Poupart's ligament on each side. Operation proved the cause of the condition to be tuberculous peritonitis with loculated ascitic fluid, but no adhesions of the gut to the parietes.

Acute Intestinal Obstruction.

In the series of cases under review there were 25 cases of intestinal obstruction. These comprised 8 intussusceptions, 3 volvuli, 7 obstructive bands, 2 cancers of the colon, 2 cases of obstruction of small gut by a gall-stone, 1 stricture of the small gut, and 2 cases of strangulated ventral or internal hernia. Six of the intussusceptions occurred in babies in whom hyperæsthesia is not demonstrable. On no occasion did I find hyperæsthesia present with volvulus, obturation of the intestine, strangulated hernia, or stricture of the small or large gut. In the four cases which did exhibit some hyperæsthesia there was in each case some peritoneal irritation. The positive findings occurred in three cases of obstruction by bands and one recurrent intussusception.

CASE 109.—A youth, who gave a history of repeated attacks of abdominal pain and vomiting, was seized with a very acute paroxysm of pain. Within a few hours a large lump was felt in the left side of the abdomen. There was no cutaneous hyperæsthesia. Operation showed an enormous intussusception of the small intestine filling the whole of the pelvis and left iliac fossa. This was reduced fairly easily. A fortnight later a similar attack occurred, and a lump again felt in much the same position. Over the palpable lump in the left iliac and umbilical region there was on this occasion definite hyperæsthesia. On opening the abdomen it was found that the intussusception had recurred, but this time there was a great deal of adhesive non-suppurative peritonitis around the tumour formed by the invaginated bowel. Reduction was effected with some difficulty.

CASE 224.—A middle-aged man suffered from traumatic rupture of the small gut which was successfully sutured by Dr. MacCormac at St. James's Hospital. A fortnight later he had severe abdominal pain and vomiting, and there was on examination a complete right iliac triangle of hyperæsthesia. At operation I found adhesive non-purulent peritonitis in the right iliac region. The appendix was adherent to the anterior abdominal wall but was not inflamed. Obstruction had been caused by some omental bands. The adhesive peritonitis was presumably the result of a latent infection due to the intestinal rupture.

CASE 248.—A lad, aged 10, who had been operated on for tuberculous peritonitis ten months previously, was seized with acute abdominal pain of a spasmodic nature. He vomited twice. There was an area of hyperæsthesia just below and to the left of the navel, corresponding to the anterior end of the tenth segment. Operation revealed about 5 feet of purplish gut strangled by a band, which was easily divided. The hyperæsthesia gradually disappeared in the course of a few days.

CASE 201.—A lad, aged 14, who had had his appendix removed for acute inflammation nine months previously, was admitted to St. Mary's with a history of two days' pain and vomiting. Bowels not open. There was extensive hyperæsthesia anteriorly from the level of the umbilicus down to Poupart on both sides—i.e., a double iliac triangle. I diagnosed intestinal obstruction due to adhesions and accompanied by irritative adhesive peritonitis. On opening the abdomen I found the end of the ileum bound down and obstructed by soft fleshy adhesions, which fixed it in the region of the appendical stump. Free fluid was present, and the whole of the right iliac region and the ileo-cæcal part of the intestines and adjacent mesentery were inflamed. The obstructing bands were broken, and the raw surfaces invaginated by sutures. Two days later the hyperæsthesia was but a band 2 inches wide above Poupart on each side. In three more days the skin sensation was normal.

From these cases it is legitimate to conclude that intestinal obstruction is not commonly accompanied by hyperæsthesia of the skin, that when it is so accompanied there is usually considerable irritation of the peritoneum, if not adhesive peritonitis, and that the area which becomes hyperæsthetic lies within one or other of the iliac triangles. In Case 248 the strangled coil of gut had a smooth peritoneal coat, and though there was much free fluid there was no adhesive peritonitis. In this case it is quite possible that a direct stimulation of the mesentery might have produced the hyperæsthesia.

Salpingitis.—Of the four cases of salpingitis (accompanied as usual by a certain amount of pelvic peritonitis) only two showed any hyperæsthesia.

CASE 91.—A woman, aged 30, who had for some days had pain on micturition, developed pain in the right iliac region and vomited. When examined there was a triangle of hyperæsthesia in the right iliac region, but the upper level of the triangle did not quite reach to the level of the umbilicus. At the operation there was much clear fluid in the pelvis, and though the vermiform appendix was œdematous the focus of inflammation was clearly the Fallopian tube.

CASE 155.—A young woman, who gave a history rather suggestive of appendicitis, exhibited a right iliac triangle of hyperæsthesia. Operation showed no inflammation of the appendix, but pelvic peritonitis and acute tubal inflammation.

Inflamed Ovarian Cyst.—Both cases observed showed a small area of hyperæsthesia.

CASE 184, in which a large ovarian cyst was found twisted thrice on its pedicle, showed a small circular area hypersensitive to pinstroke and pinch midway between the umbilicus and the anterior spine. The appendix was not inflamed.

CASE 58.—A woman, aged 31, presenting symptoms resembling those of acute appendicitis, was found to possess hyperæsthesia over an area midway between the twelfth rib and the iliac crest on the right side posteriorly. Operation showed the appendix somewhat inflamed externally, but not within. Though the Fallopian tubes were not inflamed there was pelvic peritonitis round the right ovary, which was thrice its normal size, and contained a blood-cyst which burst on manipulation. One cannot draw any conclusions from such slight data.

Renal Cases.—Two cases of renal colic showed extensive hyperæsthesia.

In Case 76 the right tenth, eleventh, and twelfth dorsal segmental areas were affected.

In Case 94 the eighth and ninth segments were also involved. Since neither of these cases were operated on one hesitates to draw any dogmatic conclusion.

In Case 279, where pyelitis and cystitis were present, there were symmetrical bands of hyperæsthesia about 2 inches broad above Poupart's ligament.

Abscess of the Spermatic Cord.

CASE 171 was interesting from the point of view of parietal inflammation causing superficial hyperæsthesia. A man, aged 34, who had had an operation for right inguinal hernia nine years previously, developed a tender swelling under the scar of the operation. He presented hyperæsthesia over the lower and inner part of the right iliac triangle extending over Poupart into the upper part of the right thigh. At operation the appendix was normal, but there was a large inflammatory mass in the position of the intra-abdominal part of the spermatic cord. This proved to be an abscess with very thick walls.

General Remarks.

From the foregoing account it is clear that in cutaneous hyperæsthesia we have an important means of assistance in diagnosis of acute abdominal disease. Since various disorders are accompanied by similar hyperæsthesia it follows that increased cutaneous sensibility must not be taken by itself to prove the existence of any particular lesion. All the symptoms must be considered together before arriving at a diagnosis. Nevertheless, in acute disorders this particular symptom can almost always be taken as signifying inflammation or irritation of a viscus or of some part of the peritoneum.

The extent of the hyperæsthesia bears no direct or constant ratio to the extent of the lesion. General peritonitis may be entirely unaccompanied by cutaneous hyperæsthesia, whilst appendicitis without any peritonitis may cause widespread bilateral cutaneous manifestations. Patients who have a reflexly active or hypersensitive nervous system are more likely to exhibit extensive hyperæsthesia. Occasionally mental shock may have an influence, as in the following:—

CASE 7.—A lad, aged 19 years, who had been prepared for operation on the mastoid antrum, was seized with acute generalised abdominal pain whilst waiting to be taken to the operating theatre. His abdominal wall was rigid all over, and there was tenderness and hyperæsthesia over the whole abdominal area, and extending on to the lower thorax. Operation showed no peritonitis, but there was an unperforated, unadherent, catarrhally inflamed appendix containing a soft concretion. There can be little doubt that the extensive rigidity and hyperæsthesia were largely the result of the mental state of a patient expecting the operation with trepidation.

I have seen the same extensive hyperæsthesia in a patient who was proved later to be hysterical. Hyperæsthesia is usually more definite and extensive in young adolescents. In acute appendicitis it is common to find an iliac triangle of hyperæsthesia in young people between the ages of 10 and 25, rather uncommon between 30 and 40, and decidedly rare after the age 40. This is but what one would expect, for the nervous system becomes less excitable as middle age approaches.

How Long Does the Hyperæsthesia Last?

Sometimes removal of the cause, such as a diseased appendix, may lead to an almost immediate disappearance of the hyperæsthesia, but quite frequently the skin only gradually returns to normal.

CASE 120.—A girl, aged 16, exhibited a complete iliac triangle of hyperæsthesia on the right side when I examined her before operation on Dec. 21st, 1921. (See Fig. 5.) On that day I removed a distended and inflamed appendix containing a concretion and showing ulceration. On the 23rd the area of hypersensitiveness had not diminished. On the 29th it had been reduced to a band about 2 inches broad above the right Poupart's ligament. On the 31st the band was only about 1 inch broad. On Jan. 3rd the hyperæsthesia had disappeared.

The delay in the disappearance of the hyperæsthesia may be of importance in diagnosis, for it may be the last symptom remaining at the time the case is examined. When a patient complains of a recent attack of abdominal pain suggestive of appendicitis, even though all the other symptoms and signs may have disappeared, the presence of increased cutaneous sensibility in the right iliac region may be almost certain evidence of subsiding appendicitis. Few cases show any abnormal skin-sensibility for more than a week after the removal of the appendix or any other cause, but I have known a fortnight pass before the normal state was resumed.

Right-sided Hyperæsthesia.

In 122 out of 136 cases showing hyperæsthesia the left side of the abdomen was normal. In one case hyperæsthesia was only to be detected on the left side, whilst in 15 cases hypersensitiveness was noted on both sides, but was more marked and extensive on the right side. Common experience informs us that there is little, if any, difference as to the normal tactile sensibility between one side and the other, and there is little reason to suppose that the viscera are only represented on the left side of the brain. Yet the great preponderance of cases showing right-sided hyperæsthesia makes it clear either that the afferent fibres from the affected viscera causing the symptom are more closely associated with the fibres from the right side of the abdominal wall or that there is some other factor which decides that the right side shall be more sensitive. Such a factor may reasonably be found in the irritation of the parietal peritoneum on the right side. In the majority of cases showing right-sided hyperæsthesia there is a right-sided peritonitis, indicated by œdema of the parietal peritoneum and serous or other effusion within the peritoneal cavity. By far the majority of cases of peritonitis are due to a right-sided abdominal lesion. It seems reasonable to conclude therefore that irritation of the parietal peritoneum may in many cases determine the presence of right-sided hyperæsthesia.

Hyperæsthesia in the Lower Abdomen with an Upper Abdominal Lesion.

The occasional presence of a hypersensitive area just above Poupart's ligament in the case of acute disease of an upper abdominal viscus (cholecystitis, perforation of a gastric ulcer) is likely to mislead unless a reasonable explanation be forthcoming. A plausible explanation suggests itself when one records the fact that in every disease of the upper abdomen which is accompanied by hyperæsthesia below the umbilicus there is to be found peritoneal irritation or retro-peritoneal inflammation extending down to the iliac fossa and sometimes to the pelvis. The affected area in these cases is usually a narrow band corresponding to the twelfth dorsal segmental distribution, and this might easily be produced by irritation in the iliac fossa where fibres of the twelfth dorsal may be distributed. The involvement of the tenth dorsal area has almost always signified extensive hypogastric peritonitis or appendicular inflammation without peritonitis.

The Nerve-supply of the Appendix Vermiformis.

Some evidence is furnished by the cases examined to show that the appendix is supplied mainly by the tenth dorsal segment and slightly from the eleventh and twelfth dorsal segments. That evidence can be summarised as follows:—

1. Whenever in a case of appendicitis there was a complete band of hyperæsthesia, extending from the middle line in front to the spinal column behind, that band always occupied the tenth segmental area on the right side. I have never yet seen a complete band corresponding only to the eleventh or to the twelfth areas in appendicitis.

2. I have seen two cases of extensive peritonitis due to appendicitis in which the whole tenth segmental area was hyperæsthetic on the right side, but the eleventh and twelfth areas were only involved anteriorly. No case of peritonitis from other causes ever showed the tenth band distinct in this way.

3. That the tenth segment is the main source of supply is suggested by the fact that there is usually a sharp line of demarcation between the ninth segmental area and the tenth on stroking from above down, whilst on stroking from below upwards the patient may not readily detect any change of sensibility—i.e., there is a more gradual threshold from below upwards, but a sudden threshold from above downwards. This would seem to be in keeping with a diminishing nerve-supply for the appendix from the tenth to the twelfth segments.

4. It is not at all uncommon in the male for testicular pain to be felt at the onset or during the course of an attack of acute appendicitis. The tenth segment is the chief source of supply to the testicle, and the occurrence of the pain is in keeping with a common segmental nerve-supply.

THE COMPARATIVE PHAGOCYTIC PROPERTIES OF THE LEUCOCYTES OF THE DIFFERENT BLOOD GROUPS.

BY F. C. MARTLEY, M.D., B.CH. CAMB.

(From the Inoculation Department, St. Mary's Hospital, London.)

WHILE investigating some points regarding the opsonic index it was borne in on me that, ceteris paribus, there was some inequality in the amount of phagocytosis displayed by leucocytes derived from people belonging to different blood groups. Accordingly I carried out a number of similar experiments to test this point, the details of the first one being as follows (the Moss nomenclature is employed) :—

I took serum from each of three normal workers belonging to group iv., iii., and ii. respectively. At the same time I prepared leucocytes from these same three by bleeding from each of them direct into citrate and washing the corpuscles obtained in normal saline ; I then made opsonic mixtures with emulsion of tubercle bacilli of all the serums, using each of the three washed corpuscles in turn, and after a suitable incubation made opsonic films which I counted, the resulting intakes of bacilli per 100 leucocytes being shown in Table I. :—

TABLE I.

Serum.	EJS corps group iv.	JS corps group iii.	FM corps group ii.
EJS .. .. iv.	 239	 302	 346
JS .. .. iii.	 245	 210	 248
FM .. .. ii.	 270	 294	 334

Taking the first column (EJS corpuscles group iv.) 100 leucocytes ingested 239 bacilli when put up with EJS serum, 245 with JS serum, and 270 with FM serum ; in other words, 300 leucocytes belonging to group iv. ingested a total of 754 organisms when put up as to 100 with iv. serum, 100 with iii. serum, and 100 with ii. serum. Similarly 300 leucocytes belonging to group iii. took up 806 organisms, and 300 belonging to group ii. 928.

Now, in each of these three cases the serums are the same, and the emulsion of bacilli is the same, the only factor that is different being the corpuscles. Hence, this experiment shows that with similar conditions equal numbers of group iv. leucocytes take in 754 organisms, group iii. 806, and group ii. as many as 928, a result which may be expressed for convenience as 100, 107, and 123, taking the group iv. figure as the standard.

Staph. = staphylococci.

I repeated this experiment several times with emulsions of tubercle bacilli, staphylococci, and coliform organisms, using the serums of various apparently normal workers, with the exception of Rb. of group i., who was a patient with some chronic tuberculous hip trouble. The results appear in Table II.

I also varied the experiment by using iv. and ii. corpuscles, and putting them both up to several different serums with the results shown in Table III :—

TABLE III.

No. cases.	Organisms used.	iv. corps.	ii. corps.
7	Tubercle.	AFH100	FM125
6	Staph.	AFH100	GD122
4	,,	AFH100	FM131

Looking down these figures it is seen that, other conditions being equal, with one exception group ii. leucocytes always ingest more organisms than an equal number of group iv. leucocytes, the average excess over the whole series being 28 per cent. In other words, while group iv. leucocytes take in 100 organisms the same number belonging to group ii. take in 128, indicating that the powers of group ii. leucocytes in this respect are decidedly in excess of those of group iv. But the question inevitably arises as to whether the various preparations are really made under the same conditions, and there seem to be three possible variations in these "same conditions" which merit investigation : (1) The leucocytic content of the bloods derived from the various groups may differ substantially between themselves, giving rise to different percentages of leucocytes in the various preparations of washed cells ; (2) the different preparations of washed cells, though intended to be made under precisely similar conditions, may, through unavoidable errors of technique bear different relations to their respective parent bloods ; (3) in preparations made with group iv. serum and group ii. corpuscles the clumping of the red cells may leave the accompanying white cells under different conditions, qua phagocytosis, to those in preparations in which there is no clumping.

To test the first point I counted the number of leucocytes in the bloods of 11 normal persons belonging to group iv. and 11 belonging to group ii. ; the average thus obtained was 8565 per c.mm. for group iv. blood, and 8195 for group ii., or in the proportion of 100 : 98 ; this difference is quite negligible, and no influence seems to be due to varying leucocytic contents in the two groups.

As regards the second point, granting that variations in the number of leucocytes makes a difference, as is certainly the case, is it likely that in some 25 cases the difference should always show itself in the one direction ? The common law of chances would lead one to expect that the differences should show themselves half on one side and half on the other, and not, as I have found, very decisively on one side of the line. Furthermore, is such variation as marked as at first sight it appears ? If an opsonic mixture is put up with a preparation of washed corpuscles, and again with the same corpuscles diluted with an equal volume of saline, the half number of leucocytes in the second preparation would not individually phagocytose twice as many as their fellows in the first ; the ratio would not be as 20 : 10, but as log 20 : log 10, as I have found in several experiments which I did to test this point. Such a variation as 100 per cent. is unthinkable in the preparation of two specimens of washed corpuscles when made carefully in the same way, and a difference of 25 per cent., which is considerable, would on this showing only produce a difference of some 10 per cent., and nothing approaching the 28 per cent. which I have found above.

To test the third possibility, that the presence or absence of clumping of the red cells may make a difference, I made experiments by putting up several serums with both group iv. and group ii. corpuscles altogether I used eight group iv. serums and eight group ii. serums. In all cases where group iv. corpuscles are used there will be no clumping, but when group ii. corpuscles are used there will be with the group iv. serums, but not with the group ii. ones. Thus, there will be two comparable series in which the

relative intakes of group iv. and group ii. corpuscles can be measured: (1) one series of group iv. serums where there will be clumpings, and (2) another of group ii. serums where there will be none. The results obtained showed that the relative intakes of group iv. and group ii. corpuscles in the first series was 100 : 126, and in the second 100 : 122. These figures do not suggest that any appreciable difference is caused by clumping of the red cells.

Conclusion. Other things being equal, group ii. corpuscles phagocytose some 25 per cent. more than group iv. corpuscles.

THE PASSAGE OF IODIDES INTO THE CEREBRO-SPINAL FLUID.

BY HENRY COHEN, M.B., CH.B. LIVERP.,
SENIOR MEDICAL TUTOR AND REGISTRAR, ROYAL INFIRMARY, AND SAMUELS RESEARCH SCHOLAR, UNIVERSITY OF LIVERPOOL.

IN his work "Le liquide céphalo-rachidien" Milian[1] summarises the work done on the "permeability of the meninges" to iodides up to the year 1905. With few exceptions it was found that in the meningitides—tuberculous, syphilitic, and meningococcal—oral administration of iodides was followed by their appearance in the cerebro-spinal fluid. In normal subjects, or those suffering from nervous diseases other than those associated with meningitis, no passage of iodides from blood to cerebro-spinal fluid could be demonstrated.

In 1916 Catton[2] published observations on the cerebro-spinal fluid of six patients having iodide medication by the mouth. Five of these, with no evidence of meningitis, taking 15–30 gr. of potassium iodide for three weeks to three months, were tapped on two occasions. At the first tapping as much fluid as possible was withdrawn. Since it had been reported by Barbat[3] that the fluid obtained from a second tapping of a patient receiving arsenical treatment was richer in arsenic than the first obtained fluid, Catton re-tapped his patients 48 hours to 10 days after the first puncture. In none of these fluids could iodine be demonstrated by the starch test after fusion of the fluid with potassium nitrate and sodium carbonate. In one patient with tabes, on oral iodide medication, an additional dose of 250 gr. failed to produce iodide in the fluids obtained 18 minutes and 24 hours later. In this case both chemical and electrolytic tests were applied; in the latter the control used was 0·01 per cent. of iodine—i.e., 10 mg. per 100 c.cm. These observations confirmed those of the older workers, but in 1921, Osborne,[4] using Kendall's method for the quantitative estimation of iodine, found that normal cerebro-spinal fluid contained an average of 0·018 mg. of iodine per 100 c.cm. of fluid. Oral administration of potassium iodide (50 to 100 gr. three hours before spinal puncture), though causing no rise (or a rise too small to be accurately titrated) in four cases, in two others caused a rise in the iodine content to 0·335 and 0·357 mg. per 100 c.cm. respectively. Two determinations on patients receiving potassium iodide by rectal administration only showed 1·808 mg. and 0·381 mg. of iodine in 100 c.cm. of fluid. Intravenous administration of sodium iodide led to a definite increase in the iodine content—from 0·400 to 2·784 mg. per 100 c.cm. It is interesting to note that in Osborne's series of cases by far the highest iodine value—42·308 mg. per 100 c.cm.—was obtained in a case of neurosyphilis, with marked meningeal involvement.

Investigation.

In view of these conflicting results, as compared with those of the previous workers, it was thought advisable to re-examine the question. Kendall's method is a long and tedious process. Moreover, as "one drop" of the titrating agent—N/200 sodium thiosulphate—is equivalent to 0·005 mg. of iodine, and the normal content of 100 c.cm. of cerebro-spinal fluid is only 0·018 mg.—i.e., 100 c.cm. of fluid is titrated with just over three "drops" of N/200 sodium thiosulphate—it was felt that, as in most cases only 5–10 c.cm. of fluid is available, which in a normal case would need only 3/20–3/10 "drops" of the titrating agent, Kendall's method was unsuitable for a general investigation.

Working on tests for iodides I have found that in the starch test the amount of nitric acid (+ nitrous acid) added is an important factor. No colour is obtained if an excess or too little of the acid be used, so that in doing the test it is necessary to add the acid drop by drop to the fluid, containing starch as indicator, until the optimum colour is obtained. Taking this precaution, one is able to detect 1 part of iodide in 200,000—i.e., 0·5 mg. per 100 c.cm. As Osborne had obtained over 2 mg. of iodine per 100 c.cm. of fluid after intravenous administration of sodium iodide, the application of the starch test as described above is sufficiently delicate to test the accuracy of his observations.

The following table shows the results of an investigation of ten cases, normal and abnormal.

Case.	—	C.cm. of 10 per cent. potassium iodide injected intravenously.	Time, in minutes, between injection and puncture.	Modified starch test.
1	Normal	50	12	Negative.
2	,,	50	35	,,
3	,,	50	45	,,
4	Tabes.	50	60	,,
5	,,	50	60	,,
6	Disseminated sclerosis.	50	30	,,
7	T.B. meningitis.	50	20	Positive.
8	,,	50	30	,,
9	Syphilitic meningitis (acute).	50	20	,,
10	Meningismus.	50	20	Negative.

In each case 50 c.cm. of 10 per cent. potassium iodide was injected intravenously; at intervals varying from 12 to 60 minutes, cerebro-spinal fluid was withdrawn and examined with the starch test: (1) directly by addition of HNO_3 (+ HNO_2), and (2) after fusion of the fluid with sodium carbonate and sodium nitrate.

Two practical points of considerable importance may here be noted. First, a trace of blood mixed with the fluid will produce a positive reaction due to the iodide in the blood; and secondly, care must be taken to see that the patient is free from organic heart disease before trying these tests, as in one case known to the writer serious consequences followed the intravenous injection of the potassium iodide.

Discussion.

The results given in the table are in agreement with those of the workers earlier than Osborne. The meningitides gave positive results; other diseases—tabes, disseminated sclerosis, meningismus—and "normals" gave negative results. Thus the rise observed by Osborne in normal cases is probably excessive. Our results indicate that if it occurs it is less than 0·5 mg. per 100 c.cm. This is of interest, since the amount contained in the blood after intravenous injection of 50 c.cm. of 10 per cent. potassium iodide is more than 100 mg. per 100 c.cm. of blood. We have thus a concentration of iodides many hundred times greater in blood than in the cerebro-spinal fluid. In view of the great diffusibility of iodides through tissue cells—witness their rapid excretion by the kidney—no physico-chemical theory of the formation of cerebro-spinal fluid will be satisfactory until it explains the phenomenon of the resistance of the cells of the choroid plexus to this salt. As a purely descriptive term "selective permeability" is doubtless unobjectionable, but when afforded as an explanation of the facts must be regarded as mere verbiage.

Clinical and Laboratory Notes.

A CASE OF PERI-ONYCHIA, DUE TO A BLASTOMYCES.

BY J. A. BRAXTON HICKS, M.D., M.R.C.P. LOND., D.P.H.,
PATHOLOGIST TO WESTMINSTER HOSPITAL;
Assisted by F. R. CHOPPING,
SENIOR TECHNICAL ASSISTANT IN THE LABORATORY.

THE following case is of interest and merits record :—

A married woman consulted me with regard to an affection of the "quicks of the nails of the right hand," which she had been told by her doctor was tuberculosis. Eighteen months before consulting me she had had a similar lesion of the left hand, the nail of the ring finger being involved, but after lasting 12 months the trouble had cleared up entirely. This freedom only lasted about a month; the present trouble then started in the right hand. The lesions on the ring and little finger of the right hand are well seen in the photograph (Fig. 1), the swelling of the peri-onychia being not so clear as the ridging and superficial destruction of the nail. She stated that they were always worse in hot weather, when her hands perspired freely, or when she had had her hands in hot water.

Bacteriology.—At the first examination very little pus was obtained, and films and cultures only revealed the presence of a staphylococcus. As heat and moisture were known to produce a free flow of pus, she was asked to foment the

FIG. 1.

Lesions on ring and little fingers, showing swelling of peri-onychia and (more clearly) ridging and superficial destruction of the nail.

fingers freely, using a saline solution. This produced a very notable reaction and a free discharge of pus. Films showed the presence of staphylococci in small numbers, and of large numbers of yeast-like bodies and mycelial threads. These were Gram-positive. A very large number of inoculations were made on a variety of media, which included several tubes of Sabouraud's maltose agar. A *Staphylococcus albus* alone grew on the ordinary media, but on Sabouraud's medium a yeast-like growth appeared after 48 hours, in addition to staphylococcus. Sub-cultures of the yeast-like growth were readily obtained on Sabouraud's agar, but not on any other medium. At first these colonies were large, white, raised, circular, and waxy, but after some three weeks they had a most characteristic appearance due to both outgrowth and (chiefly) downgrowth of radiating fern-like processes (Fig. 2). These downgrowths penetrated quite deeply into the medium, giving the culture a very pretty appearance. The surface growth of such colonies was composed chiefly of spores, while the deeper growth was made up of both branching mycelium and spores. After several sub-cultures the organism was induced to grow on gelatin, and in the sugars, but it was quite six months before it could be grown on agar-agar. On the gelatin and the agar it grew very similarly to Sabouraud's agar, save that the frond-like downgrowths were comparatively feeble. In the sugars the mycelial elements predominated. Gelatin was not liquefied; acid, but no gas, was formed in glucose, lactose, sucrose, and

FIG. 2.

Sub-culture of yeast-like growth on Sabouraud's agar, showing characteristic appearance of outgrowth and downgrowth of radiating fern-like processes.

mannite, but not in dulcite. Growth occurred best at 28° C. During the course of the treatment of the case the same organism was obtained three times from the pus in culture. We observed the cultures over a very long period, and were struck by the tendency, as time went on, for sub-cultures to become largely mycelial and even almost bacillary in type. Finally the organism declined to grow in sub-culture at all. This organism would appear to belong to the genus Monilia, variety of Link, but classification is notoriously difficult.

The lesion resisted all treatment until iodine was tried locally, and the preparation suiting it best was collosol iodine oil. The patient has been under observation for over two years, and up to date there is no report of a recurrence.

A CASE OF TRAUMATIC LACERATION OF A HYDRONEPHROSIS.

BY W. GIFFORD NASH, F.R.C.S. ENG.,
SURGEON, BEDFORD COUNTY HOSPITAL.

Mr. H. W. L. Molesworth, of Folkestone, recently described[1] a case of traumatic rupture of a hydronephrosis and stated that he knew of no English case or specimen which illustrated this accident. The case I am about to relate differs from those quoted by Mr. Molesworth in that the laceration did not involve the whole thickness of the hydronephrotic sac.

A married woman, aged 48, on June 22nd, 1904, while running at a school treat, fell forwards, her abdomen striking the ground.

Condition on Examination.—The late Dr. Horace Savory saw her the same evening on account of abdominal pain and vomiting. The pulse was 80, and there was hæmaturia but not much collapse. Nothing could be felt in the abdomen.

[1] THE LANCET, 1923, ii., 224.

On the 23rd the morning urine contained blood, but at midday it was clear. A lump could be felt in the right half of the abdomen. In the afternoon I saw her with Dr. Savory. A large movable lump occupied the right loin, extending inwards as far as the umbilicus. The vomiting had ceased and the urine was almost clear. Temperature 99·4° F. We obtained a history of an attack of pain in the right loin 26 years previously, a second severe attack three or four years later, and in the last 13 years occasional mild attacks of pain and a swelling had been noticed. This swelling was evident a week or ten days before the accident.

Course of Case.—Our diagnosis was that a hydronephrotic kidney had been bruised by the fall. On the 24th and 25th the swelling remained much the same, and the urine contained blood. On the 26th vomiting recurred and the pain increased. The urine was very dark and blood-stained, and the swelling much larger and more tender. Operation was decided on that day.

Operation.—An incision was made in the right loin, and a large hydronephrotic kidney exposed. It was incised and bloody urine escaped. The kidney was removed, and the wound closed. The hydronephrotic kidney measured 8 × 5 × 4 inches. The pelvis was very dilated, and the whole kidney sacculated. In the floor of the pelvis was a laceration about an inch and a half long, from which, no doubt, the bleeding took place.

The patient left the nursing home in three weeks and has remained well.

FIVE CASES OF PSEUDO-HYPERTROPHIC MUSCULAR ATROPHY.

BY R. LEONARD LEY, M.B., B.C. CAMB.,
ASSISTANT SURGEON, GREAT YARMOUTH GENERAL HOSPITAL.

THE following five cases of this disease, all of facio-scapulo-humeral type, have been seen by me at various times during the past three years. The cases are all boys of ages ranging from 14 to 5 years, belonging to two families of which the mothers are sisters. The grandparents were healthy and I can find no record of other cases in the family.

The grandparents had four daughters; one is married without children, another is married with several healthy male children of ages ranging from adult life to babyhood.

The third sister has two children, both boys; of these, one, aged 14, has had the disease for six years and is now helpless, but still has large buttocks and calves, and when I first saw him had the characteristic "swagger" gait, he climbed up himself to reach the standing position, and had the characteristic slackness about the shoulder-girdle with an expressionless face. His brother is 11 years old, has had symptoms for two years, and is now in the most marked stage with all the classical symptoms.

The fourth sister has four boys. One, aged 14 years, has had the disease for two years. Is still capable of walking. The second boy, aged 10 years, has been affected for 12 months and has typical manifestations. The third boy, aged 5 years, has large calves and buttocks. He climbs up himself and is, I think, affected, but the accuracy of the diagnosis is open to objection on the ground that he may be imitating his brothers. The youngest child is as yet unaffected.

The two sisters whose children are affected are very alike and both dark. The sister whose family is unaffected is fair and quite unlike the other two.

THE INTERNAL SECRETION OF THE TESTIS.—In Mr. Kenneth Walker's article published in THE LANCET of Jan. 5th, Figs. 4 and 5 appeared transposed, the section of the testis of a child of 3 being described as that of a fœtus, and vice versa. The transposition rendered meaningless the parallel drawn by Mr. Walker between the testis of a fœtus and that of a mole in the resting state.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

ON Jan. 8th the Sections of Medicine, Neurology, Obstetrics and Gynæcology, Psychiatry, and Surgery held a joint meeting at 1, Wimpole-street, W., to discuss

POST-OPERATIVE AND PUERPERAL MENTAL DISORDERS.

Dr. T. B. HYSLOP opened the discussion from the chair. With reference to these disorders, he said, there was probably not much difference of opinion between members of various sections as to the influence of heredity. With regard to the mental factors of causation, they were probably also all agreed that certain degrees of anxiety—such as that associated with the bearing of an illegitimate child—were sufficient in themselves to produce a certain mental colouring which led to mental disorders. The effects of severe labour, of suppression of the lochia, of previous attacks of insanity, were known; it was said among alienists that when a woman developed the habit of mental disorder when bearing a child, it was well to let her wait two years before again becoming pregnant, in order that the memory of the previous pregnancy might be obliterated. The question arose as to whether mental disorders of the puerperium occurred oftener in primiparæ than in other women. There was an old Scots saying: "Look out for the brown-eyed puerperal"; and he had found that a large proportion of sufferers from puerperal insanity were actually brown-eyed. From the clinical point of view, alienists now noted a comparative absence of the acute febrile puerperal condition; was this due to a subtle change in environment, or to a change in methods of dealing with these cases? He had observed that the puerperal attack of insanity frequently began in the night hours; the patient woke up insane, became violent, and might attack those around her, or might commit infanticide. In the latter event the case then became medico-legal. The puerperal homicidal case was most painful; the patient's symptoms might disappear before her trial, but she would be found "guilty but insane" and sent to Broadmoor during His Majesty's pleasure. He would like an expression of opinion concerning the duration of these types of mental disorder; alienists had come to recognise a three months' type, a six months' type, and so on—none of them necessarily incurable. He found himself at variance with the legal view concerning these cases, but he felt that until there was more enlightenment in the law courts it was more productive of good for medical men to keep to discussion of clinical and pathological phenomena.

From the Surgical Side.

Sir CHARTERS SYMONDS said he should deal with the subject from the surgical side only. In 40 years' experience of surgical operations he had only met with four cases of mental disturbance directly resulting from operation. The first of these was a man over 60, who had had prolonged intestinal obstruction. At operation there was an enormous evacuation of material; this case might have been due to toxæmia. The patient had to be moved to the strong room: his mental disturbance was of a type allied to delirium tremens, but he could sometimes be engaged in conversation. With good nursing he was perfectly well in six weeks, and remained well for 18 months afterwards. In this case there was no general septic state at all. In the second case the antecedent condition of the patient was interesting; she was a girl of 20, who had appendicitis with much suppuration. Her disorder took the shape chiefly of delusions; it supervened the day after the operation, the patient becoming noisy and difficult to feed. She was clearly of an emotional type, unstable and given to writing

stories; her mother and sister were sensible women, but her father's mentality was unknown, he being dead. The third case was in a highly intellectual man of over 70, who after operation went on well for eight days; he (Sir Charters Symonds) returned from a few days' absence to find the patient insane, the main feature of the case being an inability to take more than small quantities of fluid. The patient finally became very thin, with extremely dry skin. He was convinced that the condition was one of post-operative mental disturbance, although the medical man in charge of the case attributed it to senility. Chance, however, put the case into his own hands, and he injected a pint of saline into each axilla. The patient, who had apparently been about to die, was better next day, and finally recovered. There was no rise of temperature throughout. Why should this patient have had the attack? The only antecedent condition was that of very high intellectual development. The fourth case was that of a very excitable Jew, who had had a great deal of trouble with his prostate, and after operation had a severe mental attack, which made it impossible for him to be kept in the nursing home. These, then, were his only four cases of what he believed to be a very uncommon condition. With regard to the allied condition of delirium tremens, he had two or three cases a year, in his ward at Guy's Hospital, in patients with simple fracture of tibia or fibula—men who no doubt drank too much, but were never ill until after sustaining the fracture. He thought that in these cases of mental disorder following operation or acute illness there was no occasion to move the patients, at least for a period of six weeks, in which they generally improved. From his experience he had gathered that the danger in this connexion was not very great.

From the Neurological Side.

Dr. JAMES COLLIER said that in his experience as a neurologist and general physician he had not found these cases common. He had not given the condition much deep thought, but from the point of view of the nervous system he had seen every portion of the brain removed in operations for tumour, and only rarely had mental disturbance followed operation. Lesions of the brain were usually associated with reduction, not with aberration, except in syphilis. Post-concussive insanity seemed never to occur after operation. He had had four cases of mental disturbance in patients with tumours; in three of these, where the tumour was of considerable size and the shock of operation violent, mania persisted until death, with slight pyrexia throughout, and no obvious cause of death was found post mortem. In the fourth case the patient recovered; here no attempt was made to remove the tumour, which was deep-seated. The patient developed delusions and became troublesome, being sent to an asylum. In six months he recovered, and remained normal for two years; this recovery took place in spite of the cerebral injury remaining. Operations on the brain gave rise to insanity no oftener than operations on other parts. He had seen melancholia following several prostate operations, and after renal operations, but none following operations on the thyroid, pituitary, and suprarenals.

From the Obstetrical Side.

Mr. ALECK BOURNE said that those morbid conditions which lay on the borders of two specialities of medicine were in danger of neglect, as each group of workers might repudiate the responsibility of special study. The ætiology and prognosis of puerperal insanity was an instance of this incomplete study and neglect of contact between two groups of special workers. He had collected a few cases of his own, and notes of others from several hospitals; the chief difficulty in producing any account of the subject was the inadequacy of the clinical notes. The records frequently gave detailed descriptions of the labours, but only the scantiest notes of the insanity or factors of ætiological importance. Another difficulty was that these patients were quickly transferred from the lying-in hospital to an infirmary at the least sign of mental disturbance, and from the infirmary they were moved to an asylum. By following patients up to the asylum it had been possible to get a fairly complete account of their subsequent history, and in a few cases he had traced patients to their homes after so long a period as 12 years. Sufficient ætiological details had been obtained in 61 cases. In few instances full accounts of antecedent conditions were obtained, but it was clear that physical puerperal diseases had played a large part as exciting causes. In nine of the 61 patients (five single, four married) no cause of any kind of insanity was apparent. The possible influence of pregnancy in the single state was suggested by the fact that unmarried patients constituted 36 per cent. of the whole number; it might be argued that mentally feeble single women were more likely to become pregnant than those in sound mental health, but that contention was not borne out by the figures; for example, of 12 patients with previous mental trouble or bad family history, only one was single. Insanity associated with puerperal sepsis lasted for many months after the fever had subsided. After uterine infection, eclampsia was the next most important organic disease. The character of labour appeared to have no ætiological significance. Primigravidæ formed 59 per cent. of the total number of cases. In 18 cases, or 27 per cent. of the total number, there was unstable mental equilibrium or bad family history; had the notes been more detailed, this number would probably have been higher. With regard to time and manner of onset, of 64 cases noted, 4 developed insanity during the latter part of pregnancy, 6 became "mental" during labour (some being eclamptic), 39 showed the first symptoms during the first week, and only 18 were first affected during the second week. Three patients became insane from three to six weeks after delivery. The manner of onset was very similar in the great majority of cases. There were usually some nights of sleeplessness, after which the patient talked with some incoherence, and quickly developed more definite symptoms, such as aversion for food and for the baby, and delusions. Later restlessness and agitation would increase; most of the patients became maniacal, a lesser number became depressed and stuporose or morbidly religious. Coming to results, sufficient details had been obtained to show a mortality of 13 patients out of 58 (i.e., 22 per cent.). Of the 13, 6 died of the effects of infection, 2 committed suicide, 2 died of cardiac failure (one after 18 months in an asylum), and in the remainder the cause of death was not ascertained. He had traced 36 patients who had survived. Of these, 28 (78 per cent.) had been discharged from asylums or infirmaries after a varying time as "recovered," while 4 were "relieved." Four patients were still in asylums in a chronic condition of insanity. Of 13 cases of uterine infection traced, 6 died and 7 recovered. Six cases of eclampsia traced had all recovered—a result which he believed was in accord with the general experience of eclamptic insanity. Of 9 patients traced who had had previous attacks of insanity or bad family history, 3 recovered, 3 were relieved, and 3 were still confined in an asylum. The average time before recovery varied from two weeks to three years, the actual average being six and a half months. Apart from eclampsia, there was little correlation between cause and length of time in the asylum. Patients who remained insane for the longest periods were chiefly those with either no obvious ætiological factors, or very slight conditions such as mild pyrexia during the puerperium; those with a hereditary factor who recovered did so in less than six months. The details of the variety of insanity were not sufficiently precise to yield any basis for formulation of prognosis. Summing up, it was possible to say that the prognosis of puerperal insanity depended first upon the severity of the organic disease. Half of the fatal cases died of some variety of infection. The majority (77 per cent.) of the survivors recovered their mental

health, though many of them might again become insane should they be subjected to another pregnancy and labour. From letters received from husbands of patients, and from asylum reports, it seemed clear that if a patient who had had previous attacks or a collateral history of insanity became pregnant subsequently she was prone again to become insane; but should insanity be only a symptom of a severe organic disease such as puerperal sepsis or eclampsia, the probability was that it would not appear again in a future puerperium.

Discussion.

Sir MAURICE CRAIG thought that the fewness of the cases of post-operative insanity seen by the surgeon was due to the fact that the surgeon did not always get to know of cases which broke down weeks or months after the operation. Mental disorders might continue for many years afterwards; he had that day seen two cases resulting from minor operations several years ago. Patients broke down from various causes; the factor of heredity might be over-emphasised, but it certainly existed. Hyper-sensitivity was also important. As to the type of patient who broke down, there was an emotional type, but it was not well to assume that a person was stolid if he presented a stolid appearance. He attached great importance to the question of sleep. Certain sedatives would in certain cases stave off an attack of insanity. Sleeplessness after operation was important; it was sometimes looked upon as to be expected, and some patients could put up with it, but others could not, and in the latter the nervous system might protect itself by producing confusion. Altered blood pressure was also of importance. Mental deterioration was sometimes so rapid, in the absence of sepsis, that there must be some cause for it. Much mental instability might be avoided if the patient's nervous make-up were inquired into before operation was attempted.

Mr. H. J. F. SIMSON congratulated Mr. Bourne on his contribution to the discussion, and said that he had made it plain that from the obstetric point of view there were two types which gave rise to insanity: (1) the puerperal form due to sepsis, and (2) those with a hereditary tendency. If insane once, should a woman be allowed to become pregnant again? He was often asked to see a patient in the fourth month who had been told on the occasion of a previous pregnancy that she must not again become pregnant. If a patient was mentally unstable this was a serious thing to say, as it tended to produce a condition giving rise to puerperal insanity. If asked by such a patient to terminate the pregnancy, he thought the obstetrician should open the abdomen, and tie the tubes at the same time, informing the patient before doing so. He agreed with Sir Maurice Craig as to the importance of sleep. After the birth of the child it was well to keep the patient under the influence of some narcotic for 48 hours, to enable her to get over the shock.

Dr. R. CARSWELL believed in the existence of a great group of cases distinct from idiopathic insanities (manic-depressive states, dementia præcox, &c.); some of these cases had just been described. Many cases of transient insanity were seen during the puerperium, notably during the lactational period; they were often associated with clearly-defined lactational exhaustion, a condition commonest among the working classes. These confused, stuporose, transitional conditions were episodic, not idiopathic; if given time the patient almost certainly recovered. The number of cases of puerperal insanity had decreased; in an extensive experience he had rarely seen a case which required to be moved from a maternity hospital. This, he believed, was because the risks of infection were lessened, whilst a general advance in obstetric practice had taken place.

Dr. C. LOCKYER emphasised the importance of puerperal infectious lesions, of which the prognosis was very grave. He would suggest that the alienist too often got cases of puerperal insanity to look after; would it not be better if a skilled obstetric physician were attached to all mental hospitals?

Mr. A. CARLESS thought that there would be much fewer cases of post-operative mental disturbance if surgeons were not in such a hurry to get patients out of the nursing home or hospital. He always kept his patients in hospital for three weeks after operation. Instead of attaching an obstetrician to a mental hospital, he would suggest the attaching of a mental specialist to each obstetric hospital.

Reply.

Dr. HYSLOP, closing the discussion, said that it had to be recognised that the individual might be, as it were, a saturated solution of nervous instability; a small factor might occasion a train of ideation producing a definite psychosis. For example, to have a tooth out might cause serious trouble; and the bearing of children must be looked at from this point of view. Again, the beneficial effects of operations of general character upon insane patients were sometimes extraordinary. It must be remembered that in country hospitals which were not near a teaching hospital it would be very difficult to obtain the services of an expert gynæcologist.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.

DIAGNOSIS AND TREATMENT OF NEURO-SYPHILIS.

A MEETING of this Society was held at 11, Chandos-street, W., on Jan. 11th, under the chairmanship of Colonel L. W. HARRISON.

Dr. GORDON HOLMES opened a discussion on this subject. He pointed out that the term "neuro-syphilis" included many conditions differing in their clinical forms, their pathological basis, and the manner in which they reacted to treatment. It included the para-syphilitic conditions, tabes dorsalis and general paralysis of the insane, on the one hand, and interstitial neuro-syphilis on the other. It was now known that even in the earliest stages of syphilis many changes could be found in the cerebro-spinal fluid. Here an increase of cells might be found in something like 40 per cent. of all cases, although, of course, the proportion of people infected by syphilis who later in life developed nervous symptoms was not nearly as high. There was no evidence that those who later in life developed any form of neuro-syphilis were those only who in the earlier stages of infection showed changes in the cerebro-spinal fluid. Consequently it must be concluded that these changes in the cerebro-spinal fluid were, from the point of view of prognosis and treatment, of relatively little importance. It appeared that changes in the cerebro-spinal fluid were valuable as a sign chiefly when found in the second or third year. All would admit that the examination of the fluid, especially an isolated examination, or examinations repeated only over a short period, must fail to give any clear indication of whether the condition was a definitely stationary disease, a disease which for the moment was stationary but might progress, or a disease which was actually progressing. Altogether, the testing of the cerebro-spinal fluid in itself could not be a reliable guide to prognosis or to treatment. The speaker said that most of the cases of tabes in which the cell count fell and the globulin content diminished were those submitted to repeated lumbar puncture. The cell content of the cerebro-spinal fluid varied considerably at different levels. The proportion of cells decreased as one descended the spinal cord, so that there was always a larger proportion in the fluid obtained by lumbar puncture than in the fluid obtained by any other means. Many of these pathological cells persisted unchanged for a long time within the fluid. If a lumbar puncture was done several times, the proportion of these cells in the lower part of the cord was drawn off, and consequently the proportion found in the later counts was reduced.

As to the influence of treatment on the cerebro-spinal fluid in general paralysis of the insane, he could not find trustworthy evidence of marked improvement in any considerable number of cases in general paralysis, or, on the other hand, that any form of therapeutics had succeeded in altering seriously the pathological changes in the cerebro-spinal fluid, unless, of course, there was repeated lumbar puncture. It was frequently forgotten that such pathological changes in the fluid did not necessarily indicate that the lesion of the central nervous system was syphilitic. In his own practice Dr. Holmes admitted to more than one serious mistake in being guided by the changes in the cerebro-spinal fluid. Since the prominence recently given in the public press to the prevalence of venereal disease the public had begun to assume that all organic lesions of the nervous system were of syphilitic origin, which was unjustifiable. In conclusion, Dr. Holmes said that the study of the cerebro-spinal fluid was no sure guide to the efficiency of treatment or prognosis in neuro-syphilis, except in the interstitial variety. Moreover, except in interstitial syphilis the diminution of the pathological changes in the central nervous system was no indication of improvement or control of the disease. On the other hand, he would insist upon intensive treatment in certain cases of tabes and general paralysis in which efficient treatment had not been resorted to in earlier stages of the disease. The most important consideration was that the patient must be treated, not the spirochæte or the actual or presumed symptoms of its activity in the central nervous system. New tests which had been introduced, especially the examination of the cerebro-spinal fluid, had made more and more necessary a clinical investigation of every case that presented any symptom of neuro-syphilis. In his experience, and in the experience of many others on the neurological side of the question, mercury was par excellence the drug with which to treat these conditions.

The Drawbacks to Lumbar Puncture.

Dr. PHILIP PANTON referred to the drawbacks of lumbar puncture, and raised the question as to whether it was justifiable as a routine practice to do lumbar puncture in order to ascertain whether or not a patient was cured. There were two strong objections to lumbar puncture as a routine procedure; first, that it was a most unpleasant operation because the patient was apt to get lumbar puncture headache in its worst form, and secondly, because even if there was a complete negative cerebro-spinal fluid it could not be definitely said that he had been cured of syphilis. Still, there were occasions when it was justifiable to examine the fluid for this purpose, since it afforded about the best evidence obtainable of clinical or visceral cure—if that expression could be used. The patient might still, however, have syphilis progressing in his central nervous system. The examination of the cerebro-spinal fluid could only be described as a guide, and not as a conclusive determination.

Dr. D. NABARRO said that he had very rarely found lumbar puncture headaches in the case of adults, and he wondered whether the cause of such headaches, when they did arise, was the size of the needle used in doing the puncture. He always used a fine-bored needle, believing that there was then less risk of any leakage taking place afterwards. He had recently done about one hundred lumbar punctures on congenital syphilitics, and he had been surprised to find the positive W.R. and other changes pointing probably to syphilitic disease of the central nervous system in children in whom he had found no obvious symptoms whatever.

Discussion.

Dr. BRAXTON HICKS said that he had recently been working with colloidal benzolene, which he had found to be more efficient than the colloidal gold test.

Dr. H. SEMON suggested that some of the reactions which were observed by the pathologists might be deceptive. The mere fact of a positive W.R. or an excessive globulin content in the cerebro-spinal fluid was not in itself of bad augury.

Dr. DENNIS VINRACE asked whether it was possible to look forward to the injection of any curative agent into the spinal cord.

Mr. L. MYERS asked whether the cases with marked changes were being actively treated by anti-syphiltic drugs like mercury or N.A.B.

Dr. FOWLER WARD considered that to prevent lumbar puncture headache it was very necessary that the patient should be kept for 36 hours after the operation in a recumbent position.

Dr. J. G. GREENFIELD said that there was no test or combination of tests in the cerebro-spinal fluid which could distingusih general paralysis from interstitial brain syphilis. Clinicians often found it difficult in the early stages to distinguish between these conditions. On the other hand, the way that interstitial syphilis improved under treatment was a good diagnostic guide. There was no evidence that changes in the cerebro-spinal fluid might be present without any disease of the nervous system at all; the only evidence was that they might be present without demonstrable disease of the nervous system. He would like to corroborate what Dr. Gordon Holmes had said about the fallacy of emphasising too much a decrease in cells or in protein as being evidence of a clinical improvement, or of the success of the attack against the spirochæte. Even in cases of acute cerebellar abscess, where the inflammation of the brain was progressing and leading to the death of the patient, he had in quite a number of cases found a drop in the number of cells and a drop in the protein on the second puncture. He thought that that was purely a mechanical effect owing to the draining away of the cells in the lumbar cul-de-sac.

The PRESIDENT asked whether Dr. Gordon Holmes could give any opinion on the effect of bismuth on disease of the central nervous system. Bismuth was more penetrating, and possibly might be more useful than mercury.

Reply.

Dr. GORDON HOLMES had had no practical experience of bismuth. With regard to the efficiency of treatment in the early stages of syphilis on the occurrence of neurological symptoms, his own tendency was to share the pessimism which at least all neurologists felt, that even the most efficient and intensive treatment was not likely to reduce considerably the number of cases of tabes and general paralysis.

DENTAL BOARD OF THE UNITED KINGDOM.—A course of four lectures, illustrated by lantern slides, on the Jaws in Health and Disease, will be delivered at various centres during January, February, and March. The first lecture of the course is on the Development, Normal and Abnormal, of the Bones around the Mouth, by Prof. E. Fawcett, M.D., F.R.S. The second, on the Growth of the Jaws and Palate, will be delivered by Prof. James C. Brash, M.D., who will also give the third lecture on the Genesis and Growth of Deformed Jaws and Palates. The final lecture on the Teeth in Relationship to the Normal and Abnormal Growth of the Jaws will be given by Mr. G. Northcroft, L.D.S. R.C.S. This course will be delivered at 5.30 P.M. in the Anatomical Lecture Theatre of the University of Bristol on Jan. 25th and Feb. 1st, 8th, and 15th, Mr. Thomas Loveday and Mr. W. R. Ackland presiding; in the Medical Theatre of the University of Birmingham on Feb. 8th, 15th, 22nd, and 29th Mr. Grant Robertson, Mr. John Humphreys, Mr. F. W. Richards, and Mr. Cal Matthews presiding; at the Offices of the Dental Board, 44, Hallam-street, London, W., on Feb. 21st and 28th, March 6th and 13th, Mr. F. D. Ackland presiding; in the Surgery Theatre of the Medical School, University of Liverpool, on March 7th and 21st, and April 4th and 11th, Prof. Richard Caton, Dr. J. G. Adami, and Mr. E. H. Mountford presiding. The course is intended primarily for dentists and medical practitioners. Dental students are invited to attend. Admission is free without ticket. A lecture under the same auspices and conditions on Changes now Affecting the Jaws and Teeth of English People will be delivered by Sir Arthur Keith, F.R.S., in the Lecture Theatre of the Royal College of Surgeons of England, Lincoln's Inn-fields, London, W.C. 2, on April 29th, at 5.30 P.M., Sir J. Bland-Sutton presiding.

Rebiews and Notices of Books.

DIABETES MELLITUS.

Its Pathology and Treatment. By GEORGE GRAHAM, M.D. Cantab., F.R.C.P. Lond., First Assistant in the Medical Clinic, St. Bartholomew's Hospital; Physician, Royal Northern Hospital. Oxford Medical Publications. London: Henry Frowde and Hodder and Stoughton. 1923. Pp. 200. 6s.

Dr. George Graham's book forms an introduction to an immense field of clinical and pathological research which may well lead, taken with the work of numerous contemporary observers, not merely to the more proper understanding and treatment of diabetes mellitus, but to the opening of many of the hitherto sealed doors that guard the secrets of animal metabolism. The use of insulin has, of course, altered entirely the outlook in diabetes mellitus; yet Dr. Graham would not have us look upon the disease as a condition caused merely by the diminished output of the internal secretion of the pancreas, nor does he regard the correct substitution-therapy by insulin in relation to diet as the final goal in treatment.

The problem of the cause of diabetes is a most complex one, and in Part I. of this book Dr. Graham emphasises the uncertainty of our present knowledge of the chemistry of the sugar in the blood, of the mechanism of its storage in the tissues, and of the regulation of its amount in the blood-stream. The work done by Cohnheim early in the century with regard to the rôle of the muscles in carbohydrate metabolism has again been brought into prominence by recent researches; the shutting out the liver from the portal circulation by means of an Eck's fistula does not apparently grossly disorganise carbohydrate metabolism. The action of the group of endocrine glands opposing the pancreas in determining the sugar content of the blood—the thyroid, adrenals, and pituitary—is shown to be very little understood. The second part of the book is concerned with the clinical aspect of diabetes, and contains some important chapters on the anomalies of the renal threshold: it has for a considerable time been recognised that certain individuals have a low threshold and so exhibit glycosuria without hyperglycæmia; they are consequently not true diabetics at all, and the converse condition is here alluded to—fortunately a rare one—in which a high renal threshold prevents glycosuria from being a symptom of hyperglycæmia.

The chief importance of the work, however, lies in the later chapters of Part II.: Dr. Graham's thesis is that treatment should be such as to enable the β cells of the islets of Langerhans to recover their lost function as far as possible. This thesis was, of course, the idea underlying the dietetic treatment of diabetes laid down both by Dr. F. M. Allen and Dr. Graham in pre-insulin days, and now also Dr. Graham would have the dosage of insulin, as well as the diet, subordinated to it. It is undoubtedly a cause for satisfaction that patients who have been having treatment according to these "ladder-diet" methods, should be treated by insulin, not as if it were a revolutionary method of treatment, but rather as if it were an extension of the modern dietetic treatment; moreover, the dangers of giving large doses of insulin in relation to a greatly increased diet have been pointed out by E. P. Joslin and others. But though there is fairly general agreement that we should not push up the dosage of insulin beyond a point which keeps a patient in a state of bodily health on a relatively low diet, the arguments underlying this agreement are various. Joslin, for instance, deprecates a fuller diet with a larger dosage of insulin, as enabling a patient to put on weight only at the expense of rendering the equilibrium of his metabolism more unstable, and he would have the "insulin-stilts" kept as short as is compatible with good health and a freedom from glycosuria. But Dr. Graham, insisting that the best use to which insulin can be put is to enable the islet cells of the pancreas to rest and recover their lost function, makes it his object to reduce the dose of insulin as soon as it has enabled the method of under-feeding to raise the sugar tolerance, and he ascribes the failure of other observers to raise the sugar-tolerance to the fact that too much carbohydrate has been given in the diet when the blood-sugar was still above normal. In support of his method he quotes cases of diabetes mellitus in which the carbohydrate-tolerance has been so raised by giving a low diet, together with a low dose of insulin, as to enable the dose of insulin to be still further reduced. Accurate reduction of the insulin dosage in relation to diet is guided by careful and frequent estimation of the fasting blood-sugar, and Dr. Graham holds out the hope that while the blood-sugar is kept normal, the metabolism of the patient will tend to approach to normal also. It is on such grounds that he conceives the possibility that insulin "plus" diet may in the end involve, not merely a substitution-therapy, similar to the treatment of myxœdema by thyroid extract, but, further, a progress towards a remedy for the disease itself, based upon widening comprehension of the underlying pathological problems.

Dr. Graham is the first to point out that his method of treatment is only on early trial, and that the evidences in its support are as yet scanty and require testing by other workers on diabetic patients over long periods of time. It has to be remembered, moreover, that the much-hoped-for raising of carbohydrate-tolerance by the modern dietetic methods of Allen and Graham before insulin was discovered was seldom realised, although much was effected in prolonging the life and bettering the general condition in many cases. Only time will show whether such a dietary plus insulin will be productive of this great result. In the meantime it must be realised that this method, if it is to be accurate, involves frequent estimations of the fasting blood-sugar, and opinions vary as to the practicability of such estimations in the midst of general practice. Diabetes in children, it will be observed, calls for special consideration: these cases are invariably severe in type and the treatment must provide for growth as well as for preservation of life. Dr. Graham suggests a relatively large protein intake in these cases—2 g. of protein per kilogramme of body-weight a day: it is to be hoped that some such rule may prove effective, pending the time when the fate of the products of protein digestion in the liver and elsewhere shall have become better understood.

Dr. Graham's book will stimulate all those who are likely to have to take charge of cases of diabetes, none the less because physiological and pathological problems involved are clearly and succinctly stated.

LATERAL CURVATURE OF THE SPINE AND ROUND SHOULDERS.

Fourth edition, revised. By ROBERT W. LOVETT, M.D., Sc.D., Professor of Orthopædic Surgery, Harvard University. London: H. K. Lewis and Co., Ltd. With 172 illustrations. Pp. xii.+218. 12s. 6d.

Prof. Lovett has revised his monograph on Lateral Curvature of the Spine, a subject on which he has long been recognised as an outstanding authority. To the average physician and surgeon the pathogenesis of scoliosis, and the treatment of the more advanced cases, have seemed to constitute a mystery understood by the few, and rendered still more obscure in the majority of the voluminous writings on the subject. In this new edition Prof. Lovett has achieved a greater simplicity in his presentation of difficult problems. This is much to be commended, as the book will now be more easily intelligible to the large body of well-trained gymnasts, who should be encouraged to use this work as one of their standard

text-books. The past decade has seen a revival of the operative treatment of scoliosis, the present aim being to produce ankylosis of the spine in the region of the deformity by one of the methods already utilised extensively in connexion with the treatment of Pott's disease. On this development the author writes in his accustomed judicial fashion, so that the inexperienced surgeon is not likely to be tempted to adopt an experimental method which at the present time is safe only in the hands of surgeons with special training. Prof. Lovett has done much in the past to emphasise the illogical nature of the treatment of advanced cases of scoliosis by gymnastics alone, and once again he shows that true improvement is to be looked for from the methods of forcible correction in plaster jackets.

L'ENCÉPHALITE LÉTHARGIQUE, SES PARTICULARITÉS EN BELGIQUE.

La clinique, la expérimentation. Par les Drs. L. VAN BOECKEL, A. BESSEMANS, C. NELIS. Bruxelles: C. Nossent and Cie. 1923. Pp. 608.

MEDICINE knows no frontiers but the intensive study of a disease new to general recognition like encephalitis lethargica in various countries of the world is of epidemiological as well as of clinical importance. Drs. L. van Boeckel, A. Bessemans, and C. Nelis have written a work of encyclopædic character on the disease, and most of the important inquiries carried out in all countries since von Economo's first report in 1917 are effectively crystallised. In particular the pioneer work conducted by the British Ministry of Health and the Medical Research Council receives recognition. Apart from the book's unquestionable claim to rank as an authority upon this disease, it is of interest to trace in its pages the manifestations of epidemic encephalitis in Belgium itself. Sporadic cases appear to have occurred from time to time in Belgium prior to the year 1919, and as in other countries form the subjects of retrospective diagnosis. During the war, with one doubtful exception, no examples of the disease were seen in the Belgian Army, and it was not until March, 1919, that it was identified at Ruddervoorde, in Flanders. Here a classical epidemic outbreak occurred, seven cases being declared in a household of ten persons in the space of a month and a half. In three other families within a month four, three, and two cases respectively appeared. The Minister of the Interior, following the English example, appointed a special medical commission to investigate the Ruddervoorde outbreak, over which Prof. van Ermengem presided, and the identity of the disease with encephalitis lethargica was established. Towards the end of 1919 many other cases of encephalitis were recognised in Flanders, and in January and February, 1920, the disease appeared equally in Eastern Flanders (Syngem, Andenarde, Antryve, Valkegem) and in the other provinces, and later it spread from the west to the east in Belgium. The authors estimate the number of persons attacked in Belgium from the beginning of 1919 to the end of 1921 at 700. The Belgian evidence, which is rich in multiple cases, agrees with the general view that the incubation period of the disease is short of less than a month's duration.

The case mortality based on the observations of 200 cases is found in Belgium to be 31 per cent. This is higher than the English figure for 1918 (22·0 per cent.) and lower than the English figure for 1920 (49·3 per cent.). The mortality depends much on the age of the patient, increasing with advancing years. As regards sex, the Belgian mortality was found to be higher in females. The clinical types of the disease were representative of those usually encountered, including examples of the myoclonic form. The authors noted in Brussels an undue incidence of polyneuritic cases of obscure ætiology occurring when encephalitis lethargica was prevalent. Without definitely pledging themselves to the identity of the two forms of disease, they incline to the view that in epidemic periods such instances of neuralgia and neuritis are due to the virus of encephalitis. Polyneuritic forms were met with in the English outbreak of 1918 associated with definite lethargic symptoms, but few have been reported since that date. In Belgium "epidemic hiccup" is regarded as a mild form of encephalitis lethargica. Out of the 200 cases of encephalitis lethargica intensively studied, 62 died of the malady. Among the 138 survivors, 104 were kept under observation for three and a half years. Of these 58 remained cured, 2 recently developed mental and ocular sequelæ, while 44 showed various mental, choreiform or paralytic after-effects. In this sad heritage, as in France, symptomatic paralysis agitans predominated, being declared in 27 cases. The sequelæ only appeared in young subjects or in adults under 50 years of age. As a rule, the mental or paralytic after-effects ensued on severe attacks of encephalitis; but paralysis agitans was only seen to follow mild cases of the acute disease or cases in which it was manifested without localising signs.

The value of the work here considered, which is published under the auspices of the Belgian Ministry of the Interior and of Hygiene, is enhanced by a complete and detailed review of the pathology of encephalitis lethargica, and critical attention is paid to the most recent researches on the subject, for example, those of Levaditi, Harvier and Nicolau, and the work of Perdrau in this country. The work is illustrated, and has both a complete index and a copious list of references.

MODERN ASPECTS OF SYPHILIS.

By M. J. HORGAN, B.A., M.B., Ch.B., B.A.O. N.U.I., late Resident Medical Officer, General Dispensary, Nottingham. Oxford Medical Publications. London: Henry Frowde and Hodder and Stoughton. 1923. Pp. 136. 5*s*.

THIS little book is based on lectures and published works of Josef Kyrle, and on practical study of the methods and material of the Finger Clinic in Vienna and sets forth the standpoint of Finger and his co-workers. The greater part of the book deals with the importance of the changes in the cerebro-spinal fluid in syphilis and their value in diagnosis and treatment. The author insists on the necessity of examination of these changes and their proper interpretation as only by this means is there any hope of avoiding late neuro-syphilitic diseases as tabes and general paresis.

Obviously, in ideal conditions, the examination of the cerebro-spinal fluid should be done repeatedly but in most cases one examination only can be done and the importance of the timing of this examination cannot be exaggerated. In this book the time of election is considered to be the second or third year of the infection. This choice will not meet universal approval. In the matter of treatment intrathecal injections are condemned entirely—this is strong but probably justifiable. No mention is made, unfortunately, of treatment by intravenous medication followed by drainage of cerebro-spinal fluid—the method of reinforcement—and apparently this method does not find favour in Finger's clinic. The chapter on allergy and the luetin reaction is short but gives much food for thought. It is unfortunate that the writer has used a term "positive liquor"—it is not an accepted expression, and is likely to lead to confusion.

On the whole this is an excellent little book and will repay careful study.

DIAGNOSTIC METHODS.

Fourth edition. By H. T. BROOKS, A.B., M.D. F.A.C.P., Professor of Clinical Medicine, College of the Medical Evangelist, Los Angeles, California. London: Henry Kimpton. 1923. Pp. 109. 8*s*. 6*d*.

THIS book is distinguished from many of its kind by its brevity and its handy size and shape. Within the space of his 109 pages the author has managed

to compress a surprisingly large number of the methods of clinical diagnosis of which the need may be felt by the practitioner. He states it to have been his aim to confine himself to those procedures not requiring much apparatus or the expenditure of much time; this being the case, he was certainly well advised to omit descriptions of the more elaborate quantitative procedures, as, for example, the estimation of the blood-sugar, the calculation of the basal metabolic rate, and so forth. He was as certainly ill-advised to include details of the technique of the Wassermann reaction and of the complement-fixation test for gonorrhœa. The most complicated of the chemical tests are child's play compared to either of these, and the possibilities of error that lurk in both, and more particularly in the latter, are such as to render them both unsuitable for occasional performance by any busy man.

Apart from these last-mentioned procedures, the descriptions of the various techniques are clear, concise, and strictly practical—so free, in fact, is the book from theoretical considerations and general principles that one rather gains the impression that clinical diagnosis is simply a matter of pressing the button and getting the answer on a card. To counteract any such tendency, Dr. Brooks suggests that his book should only be used in conjunction with "some extensive work on clinical diagnosis." In this he is undoubtedly right.

DIE CHIRURGIE DES ANFÄNGERS.

By Dr. GEORG AXHAUSEN, A.O. Professor für Chirurgie in der Universität Berlin. Berlin: Julius Springer. 1923. Pp. 443. $4.50.

THIS book consists of lectures given by Dr. Georg Axhausen to his students in the University of Berlin. The lectures were intended for the beginner—that is, students commencing their clinical work—and as Dr. Axhausen says in his preface, "if students will read through the book in the holidays before they begin their clinical course, its object will have been fulfilled." The book is admirably adapted for the purpose. It does not deal with treatment, but only with methods of examination, and the deductions to be drawn from the signs found. Especially well described are the methods of examination of the hip-joint, and excellent diagrams are given to illustrate and explain Trendelenburg's sign, a useful and important test that is often omitted in text-books. There is a short chapter on minor surgery, such as the student is called upon to perform, including the necessary local anæsthesia.

Of its kind, this is one of the best books we have seen, and it might repay translation into English. The book is short and is easily read, and a student about to start work in the wards would find it an invaluable companion during his first surgical post, giving the solution to many problems and perplexities during his initiation into ward work.

TEETH, DIET, AND HEALTH.

By KURT H. THOMA, D.M.D., Assistant Professor of Oral Pathology, Harvard University Dental School. London: Werner Laurie. 1923. Pp. 226. 10*s*. 6*d*.

THIS book is public rather than scientific in its appeal, and it is highly desirable that the public should be instructed in the elements of the anatomy and pathology of dental disease, for its prevention, so far as our knowledge of its causation permits, rests with the public rather than with the professional hygienist. The book demands a modest standard of knowledge on the part of its readers, but it is clearly written in non-technical language. The statements are soberly expressed, while there is little to indicate, except in reference to various articles of diet not common in this country, that it is an American and not a British production.

We notice that Dr. Thoma uses the "slogan," a clean tooth never decays. In our view it is a somewhat misleading phrase likely to convey a false sense of security. Cleanliness in the sense implied is beyond the reach of the most thorough dental hygiene, while there are some puzzling anomalies; it is not uncommon to see mouths which are kept as clean as is possible, with many carious teeth, and others quite uncared for with entire immunity. To those who are under the illusion that dental conditions are better in the United States than in this country, it may come as a surprise to hear that dental disease is just as common. Statistics at the Mayo Clinic showed that 87 per cent. of patients suffered from infected teeth, while out of 846 children in Cleveland, only three were found with perfect teeth. Even English statistics do not show such a high incidence of dental disease as this, though possibly the American standards are higher. In an account of the evolution of the teeth we are told that the canines are formidable weapons in the boar, *elephant*, and walrus. The tusks of the elephant are, of course, incisors. We dissent from the statement that the first permanent molars begin to calcify ten weeks before birth. C. S. Tomes says that calcification commences in these teeth just before birth, and N. Bromell gives the date as one month before birth. Again, the statement that all the permanent teeth, with the exception of the first molar, commence to calcify after the first year seems to err in the other direction. All the authorities on dental anatomy agree that calcification of the incisors commences during the first year. It is interesting to note that the author holds that sugar does the greatest harm by attracting free lime salts in the body so that the teeth may be imperfectly calcified. Not every dietitian will agree with him that sugar is not a natural food and should have no place in the dietary.

If all parents studied this book the task of the dentist would be made easier. The chapter on Mouth Hygiene is full of practical details. The proper way to brush the teeth is illustrated by some good diagrams. In view of some recent correspondence in our columns, it is interesting to note that Dr. Thoma advocates brushing the gums as well as the teeth. The book is well printed and the illustrations are good. Altogether it is an excellent production.

THE PHYSIOLOGY OF MUSCULAR EXERCISE.

By the late F. A. BAINBRIDGE, M.A., M.D., D.Sc., F.R.C.P., F.R.S., Professor of Physiology, University of London. Second edition, revised by G. V. ANREP, M.D., D.Sc. Lond., Senior Assistant in Physiology, University College, London. London: Longmans, Green and Co., 1923 Pp. 226. 10*s*. 6*d*.

MOST physiologists are in agreement that the author of this work, one of the most gifted physiologists in the country, gave us in this book one of the best monographs on physiology ever written in any language. The early exhaustion of the edition gives further proof of this. In the present edition some nine pages of text have been added, there is one new figure, and the index has been improved. The added matter consists chiefly of references to English work by Hill, Lupton, Anrep and Cannan, Douglas and Haldane, and Barcroft. There are also references to the work of Krogh on capillary reactions and of Krogh and Lindhard on the respiratory quotient. Apart from these additions the editor has left the text as it stood, and in our opinion he has been wisely advised in this, for it could not well have been improved.

BLOOD CHEMISTRY, COLORIMETRIC METHODS.

For the General Practitioner. With Clinical Comments and Dietary Suggestions. By WILLARD STONE, M.D., Attending Physician, Los Angeles General Hospital, U.S.A. New York: Paul B. Hoeber, Inc. 1923. Pp. 75. $2.25.

THIS book gives a good account of the methods which are in use in the United States for estimating the non-protein nitrogen, urea, uric acid, creatinine,

sugar, cholesterol, and chloride, which are present in blood. In nearly every case the final determination depends on the use of a colorimeter. The description of the method is clear and concise, and will save the laboratory worker much trouble in looking up the original papers, the reference to which, however, is always given. Although many of the methods are not by any means too difficult for the practitioner to learn, the time factor may prevent his attempting to use them. The suggestion that an assistant could easily learn to carry out the technique is a practical one. A short account of the clinical value of the estimation is appended to each section, and these seem to be carefully considered. Some 20 pages are devoted to the question of dietary control of disturbances of metabolism. The most important part is that concerned with the acid and alkali content of the various foodstuffs, and tables are given showing the acid and alkali produced by different foodstuffs. Joslin's tables for the treatment of diabetes are given in preference to Allen's.

The book is typically American in many of its phrases, and some unusual words are used, but on the whole it reads easily. It should be of considerable value both to the laboratory worker and to the clinician.

WHY BE FAT?

By CECIL WEBB-JOHNSON, M.B., Ch.B., Major, R.A.M.C. (T.F.), late Civil Surgeon and Officer Commanding Station Hospital, Dum-Dum. London: Mills and Boon, Ltd. 1923. Pp. 174. 5*s*.

THIS book should find a ready sale among those who suffer from obesity—it is well and wittily written, and contains a great deal of useful matter. The advice given by the New York editor, to anyone wishing to get thin, "(1) eat everything you don't like, (2) do everything you don't want to," is by no means the correct treatment. The main lines recommended by the author are, to eat less of everything, and, what is equally important, to drink much less of everything, to sleep less, to take more exercise, to take cold baths, and generally lead as healthy a life as possible. The author condemns milk in such strong terms as to give the impression that he is the victim of an *idée fixe* on the subject. He even goes so far as to say that, in his opinion, milk is the chief cause of cancer of the stomach and bowel, besides being the commonest cause of dental caries and pyorrhœa. This violence is a defect in a book otherwise wholly sensible and well written.

THE FIGHTING INSTINCT.

By PIERRE BOVET, Litt.D., Professor of the University of Geneva, Director of the Jean-Jacques Rousseau Institute, Geneva. Authorised English Translation by J. Y. T. GRIEG, M.A. London: George Allen and Unwin. 1923. Pp. 252. 10*s*. 6*d*.

THIS book, by a Swiss educationist, was prompted by the European war, and the thought that the investigation of its immediate causes should give place to a more general inquiry. Certain truisms had assumed the authority of common sense: that man's pugnacity made wars inevitable; that political States regressed to infantile modes of behaviour, and let themselves go in outbursts of destructive anger; or that the future depended upon pacificist teaching. With these propositions as a starting point, Mr. Bovet makes a thorough examination of the fighting instinct in its different modifications and sublimations, and applies the teachings of modern psychology as a means of understanding human behaviour. He draws upon many writers, and gives the impression that he uses them not to find support for his own views, but for what he can learn from them. Unfortunately, the word "pacificist" has acquired a narrow and controversial connotation; but in the proper sense of the word all good citizens are pacificists, and few would wish to reject the conclusion that "The pacificist ideal is in the line of human development, such as this is shown to be in individual and social psychology."

The book is neither Utopian nor a sentimental plea for peace, but a scientific and practical exploration of the possibilities of so controlling our social heredity as to render possible a society of nations in which armed conflicts will no longer arise. The translator has done his work well, and the book deserves a wide circulation.

JOURNALS.

BRITISH JOURNAL OF CHILDREN'S DISEASES, October to December, 1923.—Dr. John Thomson, of Edinburgh, contributes a paper on Peculiar Fatal Convulsions in four children, whose father suffered from lead poisoning, in which the chief points of interest are as follows: (1) All the children born after the father's lead-poisoning began were similarly affected, although the mother remained quite healthy; (2) the child whose case is described continued until near the end in excellent bodily and mental health apart from fits, and showed no signs of rickets, indigestion, mental dullness, or mental peculiarity; (3) the attacks were very different in their phenomena from ordinary infantile convulsions, affecting the respiratory apparatus specially and yet not resembling those in laryngismus or status lymphaticus.—In a paper on Severe Tuberculin Reactions, Scrofula, and Status Lymphaticus, Dr. Charles McNeil, of Edinburgh, states that in a small number of cases of tuberculous infection the tuberculin cutaneous reactions are remarkably severe. In the majority of these severe tuberculin reactions the type of lesion is that formerly described as scrofulous, and commonly includes a scrofulous or phlyctenular conjunctivitis. Dr. McNeil recommends that the term "scrofula" should be retained to describe those types of tuberculous infection which are associated with the status lymphaticus, and which in consequence exhibit an intensified reaction to the tubercle bacillus and its poisons.—Dr. Norman B. Capon, of Liverpool, reports a Case of Tuberculosis in Infancy to illustrate the diagnostic difficulties presented by tuberculosis at that age. He points out that though the condition may be strongly suspected when the child's mother is proved conclusively to be the subject of active tuberculosis, it has no definite symptomatology, pallor, wasting, enlargement of the liver and spleen being the most frequent findings. In Dr. Capon's case, in which death took place 41 days after birth, it was impossible to state definitely the route by which infection occurred, especially as the placenta was not examined histologically; but the advanced state of the lesions in the child's viscera was in favour of the infection having been intrauterine.—In a paper on Dilatation of the Aorta in Children Associated with Chronic Interstitial Nephritis Dr. J. H. Sheldon, of Wolverhampton, reports a case in which dilatation of the aorta in a boy, aged 10, was produced by the high blood pressure resulting from chronic interstitial nephritis. All other causes of aortic dilatation could be excluded such as syphilis, acute infections, congenital malformation, and arteriosclerosis. He alludes to a similar case reported by Evans, and states that in both cases the structure of the aorta post mortem showed very little departure from the normal, indicating that the dilatation was probably a mechanical consequence of the hypertension.—Dr. Angelica Panayotatou, of Alexandria, reports a cases of Typhoid Fever Complicated by Purpura Hæmorrhagica. The patient was a girl, aged 4, who on the fourteenth day of disease developed ecchymoses on the chest followed by epistaxis, melæna, and hæmorrhages from the ears. Various modes of treatment were employed without success, and death took place on the eighteenth day of disease.—The abstracts from current literature are devoted to nervous and mental diseases.—A very full index to the volume forms a useful guide to contemporary pædiatric literature.

The Conduct of Medical Practice.

A Series of Articles by Experts dealing with the Difficulties Encountered in Professional Life and How to Meet Them.

III.—STATUTORY OBLIGATIONS: HOW TO FULFIL THEM.

BY JAMES NEAL, M.R.C.S. ENG.,
GENERAL SECRETARY OF THE MEDICAL DEFENCE UNION.

It is an honour for a man to keep aloof from strife.
Proverbs xx. 3.

I AM convinced that most of the medico-legal difficulties met with in medical practice are preventable. Many are due to sheer carelessness or slackness, possibly to overlooking some small point which at the time seems unimportant, but which subsequently proves to be vital; some to a want of knowledge of the various statutes that directly affect a medical practitioner in the daily exercise of his profession. In some respects it is unfortunate that the teaching of law is not a part of the medical curriculum. A certain amount of law is taught to those who are training to become accountants, bankers, surveyors, and others, but it is a subject which is almost entirely neglected in the case of the medical student.

The General Medical Council.

Every medical practitioner should know the functions and powers of the General Medical Council; the privileges and obligations which he acquires by the act of registration; his responsibilities in the treatment of his patients; and his duties with regard to certification of all kinds. The Council was established by the Medical Act of 1858. It consists of 38 members. Essentially it is a council of education and registration. It exercises supervision over the various qualifying bodies, and it prepares and publishes the Medical Register. No matter what medical diplomas or degrees a man may have obtained, he is not legally entitled to style himself doctor or surgeon, or to practise as such in this country until his name has been entered on the Medical Register.

The Council has no control whatever over unregistered practitioners, but, by virtue of its power to erase from the Register the name of any medical practitioner adjudged guilty of "infamous conduct in a professional respect," it exercises a disciplinary control over the medical profession. In such cases it is the sole judge of all questions of fact, and there is no appeal from its decision on a question of professional conduct arrived at after due inquiry at which the accused person has had a full opportunity of being heard, and of which he has received due notice. The Council cannot take evidence on oath, it has no power to compel the attendance of witnesses, and it cannot award any costs.

Registration and its Effect.

The medical student who passes his final examination and obtains a degree or diploma should register before he commences any kind of professional work. The procedure to effect registration consists merely in forwarding an application to the Registrar of the General Medical Council* with the statutory fee of £5 1s., and this should be done at the earliest moment possible after becoming qualified. Once registered, it only remains for the practitioner to keep the Registrar notified of any change of address, and to reply to any formal inquiry which he may receive from the Registrar as to the correctness of the entry of his name and address in the Register.

By the act of registration the practitioner acquires certain privileges and certain obligations. He becomes entitled to practise medicine, surgery, and midwifery in the United Kingdom, and, subject to any local laws, in any other part of the British Empire. He can sue for fees, unless he is a Fellow of the Royal College of Physicians, in which case he is prohibited by by-law from recovering at law his expenses, charges, or fees. He can fill public medical appointments. He can sign medical certificates in certain cases, including lunacy (if in practice), death, vaccination, and other statutory certificates. Whilst he remains in practice he is exempt, if he so desires, from serving on juries. It is necessary, however, that his exemption should be claimed when the lists are revised, for if his name is included in the lists he will be liable to serve.

The obligations to the State which devolve upon a registered medical practitioner may be placed under seven headings.

1. *Notification of Births.*

A medical practitioner who is in attendance upon the mother at the time of, or within six hours after, the birth of a child, must give notice in writing of the birth to the medical officer of health of the district, unless he has reasonable grounds for believing that notice has already been duly given by some other person. The practitioner should therefore ascertain whether the father or nurse has given the required notice, and, if not, he should send the notice himself. Too often this precaution is neglected, with the result that, owing to the default of others, the practitioner finds that he is held to have committed an offence, and rendered himself liable to a fine. All births after the twenty-eighth week of gestation must be notified, whether the child was born alive or dead. A stillbirth of less than 28 weeks' gestation need not be notified. No charge can be made for the notification of births.

2. *Death Certification.*

In the case of any person attended during his last illness by a registered medical practitioner, that practitioner must sign and give to some person, required to give information concerning the death, a certificate stating to the best of his knowledge and belief the cause of death. When the practitioner has not actually seen the dead body, and is consequently not in a position to testify as to the fact of death, he should invariably insert the words, "as I am informed" in the certificate. No fee can be charged for furnishing the statutory death certificate, though any additional certificates of death required by the relatives may be charged for. Any death certificate required under the Friendly Societies Act must be a "certified copy" issued by the Registrar of Deaths, and not a duplicate copy of the statutory death certificate signed by the attending practitioner. The statutory death certificate cannot be refused on the ground that the practitioner's account for professional services has not been paid.

3. *Inquests.*

An inquest must be held when "there is reasonable cause to suspect that a person has died either a violent or unnatural death, or has died a sudden death of which the cause is unknown." In any such circumstances the practitioner should refuse to give a certificate and should inform the coroner of the facts. If the practitioner is informed that his presence will be required at the inquest, he should insist upon being served with a subpœna, as otherwise he will not be able to enforce his claim for his fee. No fee is payable to a medical witness at an inquest on the body of a person who died in a public institution, if it was the duty of the medical witness to attend the deceased person as medical officer of the institution. When a medical practitioner has reported a death to the coroner, there is no legal obligation upon the practitioner to give any further information until he is on oath in the witness-box, but as a matter of courtesy it is customary to answer any questions put by the coroner or his officer. No fee can be demanded for information given in such circumstances.

* 44, Hallam-street, London, W. 1. The address of the Registrar of the Branch Council for Scotland is 20, Queen-street, Edinburgh, and that of the Branch Council for Ireland, 35, Dawson-street, Dublin.

4. *Notification of Infectious Disease.*

It is the duty of every medical practitioner attending on or called in to visit a patient, on becoming aware that the patient is suffering from an infectious disease scheduled under the Act, forthwith to send to the medical officer of health for the district a certificate stating the name of the patient, situation of the building, and the infectious disease from which, in the opinion of the medical practitioner, the patient is suffering. Similar notifications must be sent to the Chief Inspector of Factories, Home Office, London, in the case of lead, phosphorous, arsenical or mercurial poisoning, or anthrax, contracted in any factory or workshop. It is customary in urgent cases to notify infectious diseases by telephone so as to secure the earlier removal of the patient to an isolation hospital. In all such cases the written statutory notification should also be made at the earliest moment possible, and neglect of this precaution frequently leads to difficulties.

5. *Evidence in Court.*

A medical practitioner may be required to give evidence in court. Such evidence is privileged to the extent that no civil action will lie against him in respect thereof, but not in the sense that he can refuse to disclose information obtained in his professional relations with his patients. A medical witness who is asked a question which he can only answer by a breach of professional confidence, should appeal to the judge as to whether he is compelled to give the information. If the judge tells him to do so, he must either obey or take the consequences, which may involve a committal for contempt of court. It is conceivable that in some cases a doctor's conscience would not allow him him to give the required evidence. All honour to those who in such circumstances steadfastly refuse to betray a professional confidence. But in many of those cases where privilege is claimed no breach of professional confidence is really involved, as no pledge of secrecy was given or implied.

In criminal cases the amount of the fees to be paid to professional witnesses is fixed by regulations made by the Home Secretary in 1904, modified to the extent of a 50 per cent. increase by the Witnesses' Allowances Order of March 1st, 1920. In civil cases in the High Court the fees allowed vary according to the professional standing of the witness, and in addition he is entitled to his reasonable travelling expenses, but the witness usually arranges with the solicitors as to the amount of his professional fee. The arrangement should be made beforehand, and a written undertaking to pay the agreed amount should be insisted upon. In default of this, it will frequently be found that the solicitors will refer the witness to their clients for his fee, when disappointment may result.

6. *Dangerous Drugs Regulations.*

These regulations impose important obligations on medical practitioners in the matter of keeping specified records of all supplies received, and of all drugs dispensed, which come within the Act. So far as is necessary for the practice of his profession, a duly qualified medical practitioner may be in possession of dangerous drugs. He may supply them by personal administration or by administration under his direct supervision, and he may dispense them for the use of his patients, except that he may not supply raw opium to a patient. A prescription for a dangerous drug:—

(i) Must be in writing and be dated.
(ii) Must be signed with the usual signature of the prescribing doctor.
(iii) Must bear the address of the prescribing doctor (except in the case of prescriptions issued under the National Health Insurance Acts).
(iv) Must state the name and address of the patient.
(v) Must state the total amount of the drug to be supplied on the prescription.

A messenger sent to take delivery of a supply of drugs must be given an authority in writing, signed by the doctor, to receive the drugs on behalf of the doctor. Except in the case of drugs administered by himself personally, a doctor who dispenses or supplies medicines is under obligation to keep the registers of purchases and supplies in the prescribed manner. All registers and other records, and any stocks of drugs held, must at all times be available for inspection by any duly authorised inspector.

Since the introduction of the Dangerous Drugs Act, medical practitioners frequently find some difficulty in deciding the extent to which they can prescribe dangerous drugs for persons addicted to morphia or other drug habits, without rendering themselves liable to have their conduct called in question. It must be assumed that a medical practitioner is entitled to prescribe whatever drugs he conscientiously believes are necessary for the proper treatment of a patient, but when the amount of a dangerous drug which he is disposed to order is in any way excessive, he will be well advised to insist that the amount shall be decided in consultation with a colleague of repute.

7. *Certification in General.*

The quasi-official status accorded to the registered medical practitioner gives him certain privileges in certifying as to his opinion with regard to the physical or mental condition of his own or others' patients. This privilege must be exercised with due care. A medical practitioner may be held liable for injury caused by his neglect to make proper inquiry before signing certificates. A certificate also, if signed maliciously and without reasonable cause, might be held to be a libel upon the person to whom it relates. In the ordinary way the High Court does not accept a medical certificate as evidence, but requires personal testimony from the medical practitioner. A medical certificate must always be regarded as a document of great importance and the practitioner should only certify what he is prepared to affirm on oath.

A HUNDRED YEARS AGO.

HOSPITAL REPORTS.

GUY'S HOSPITAL (Jan. 16).

Amputation at the Hip Joint.

This formidable operation was performed here this morning, for the first time, by Sir Astley Cooper in the presence of some of the surgeons and pupils belonging to these institutions . . . the femoral artery, being tightly compressed at the groin by an assistant (Mr. Key), Sir Astley, standing to the outer side, with the limb in the one hand, and the catlin in the other, commenced the operation, by making an incision just below Poupart's ligament, a little to the iliac side of the femoral artery; this was continued obliquely downwards and outwards to the back of the thigh, about one-third of the way down, from which point the knife was carried in the opposite direction, obliquely upwards and inwards to meet the first incision, by this means, forming an elliptical curve; at this step of the operation, the femoral artery was divided, to which a ligature was immediately applied; the cellular membrane was merely cut through at first, but the knife was again carried in the same direction as before, and thus the muscles were also separated; at this step also, it was necessary to apply another ligature on the inside of the limb; here the operator changed positions, and sat on a chair in front of the patient, and waited a short time to see whether there were any bleeding vessels; after the lapse of a few minutes the operation was continued and very shortly completed, the head of the thigh-bone being removed from the acetabulum without any difficulty; two ligatures in addition to those already used were applied, making in the whole four; the integuments were brought together, and a suture applied to the upper portion; strips of adhesive plaster, and lastly a bandage were put over the stump. There were about 12 ounces of blood lost, but it had the appearance of being venous. The limb was removed in the space of twenty minutes, the securing the arteries and dressing occupied fifteen more . . . During the operation the man was extremely faint, but some wine being given him, and fresh air admitted, he recovered. The patient bore the operation with extraordinary fortitude, and after all was finished, he said to Sir Astley, "that it was the hardest day's work he had ever gone through," to which Sir Astley replied, "that it was almost the hardest he ever had."

LONDON: SATURDAY, JANUARY 19, 1924.

IMMUNISATION AS A BUSINESS PROPOSITION.

AMERICA is alive to the social value of health. Dr. C. E. FORD, president of the American Association of Industrial Physicians and Surgeons, has recently[1] dwelt on knowledge acquired from industrial investigations; he shows not only how there is a constant ratio between length of employment and physical soundness, but how the sickness rates of the general community and infant mortality are affected by earnings. A sickness rate of 70 per 1000 accompanied a wage of less than $12 per week, but it fell steadily as wages increased until it became only 18·5 for a wage of $20 or more; while an infant mortality of 137·8 went with yearly incomes of $1050, but was only 89·4 for incomes of $1850. The figures are striking, and indicate the enormous importance of real wages to public health and of the study of medical sociology. This country is falling back both in the practice and study of preventive medicine as a money-making concern.

In a well-known American periodical, *Munsey's Magazine*, an advertisement has been appearing regularly in recent numbers. The Metropolitan Life Insurance Company of New York finds it worth while, in the full-page advertisement referred to, to draw attention to the risks of diphtheria and the advantages of immunisation by toxin-antitoxin mixtures. This company, it is stated, "is making every effort to teach mothers that this disease is entirely preventable, and urges them, as well as others in charge of children, to take no chances with diphtheria." Between 1911 and 1922 the death-rate from diphtheria of children insured in the company declined 34·1 per cent. and is still lower in 1923, and it is only reasonable to assume that this improvement is due, in part at least, to an increasing appreciation of the importance of early serum treatment and to the consequent immunisation of very large numbers of children in all the great American cities. In advocating the general application of the Schick test and of the toxin-antitoxin method of prophylaxis the advertisement asserts that "experience shows that both test and treatment are painless and harmless," a claim which will be endorsed, so far as young children are concerned, by those who have employed the method in this country.

It is to be regretted that Great Britain has fallen so far behind the United States in this matter of diphtheria prevention. During the war the medical profession was too over-worked to undertake any investigations which had no direct bearing on that great struggle, and as a result it was not until 1920 that the first account of work done on the Schick test in Great Britain, a paper by Dr. H. MASON LEETE, appeared in these columns. America had a long start and now, after nearly ten years' work, is achieving wonderful results. New York expects to immunise 100,000 children of school age, and 20,000 under school age, in the coming year. Dr. W. H. PARK reports that the death-rate from diphtheria per 100,000 inhabitants has fallen from 22 to 15 in the last four years, and work as extensive and effective has been undertaken in many of the States. To compare with this we have little to show in this country, although Dr. R. A. O'BRIEN and his colleagues have worked energetically at the subject and their published results have doubtless encouraged others to make a trial of prevention methods. Some of the large fever hospitals have taken up the question, and we understand that in those of Aberdeen and Edinburgh all nurses are now protected, the results so far attained having been most encouraging. In both cities, moreover, the departments of child welfare have started immunisation, but much propaganda work will be necessary before parents and directors of institutions see the advisability of imitating America. For their persuasion advertisements of the type of that of the Metropolitan Life Insurance Company might be effective. The company certainly would not advertise unless firmly convinced that it was a paying proposition, and thoughtful parents and guardians, who might be inclined to regard immunisation as a medical fad, are likely to be impressed by such outside testimony. The pioneers of diphtheria prevention in this country, however staunch their patriotism, must regard the enterprise of this and other American insurance companies with envy, and heartily wish that by some process of inoculation or otherwise they could induce our own to copy the methods.

[1] Journal of Industrial Hygiene, December, 1923, v., 279–287.

THE GUINEA-PIG AS INDICATOR.

THE last issue of THE LANCET contained an article, by Dr. E. H. KETTLE, on the Criteria of Cure in Tuberculosis of the Guinea-pig, which is of special importance at the present moment when large numbers of experimental tests of various antigens and chemotherapeutic remedies are being made. Dr. KETTLE wisely points out that guinea-pigs are as a rule experimentally infected purely for diagnostic purposes, and not with the object of studying the whole process of disease in this particular animal. Having obtained what they require—viz., unequivocal evidence of tuberculous infection, most laboratory workers are not further concerned with the trend of events in the animal, any more than a chemist who obtains a precipitate in a test tube is concerned with the physics of the phenomenon of precipitation. But it appears clear that if the guinea-pig is to be used as a test animal for the assessing of anti-tuberculosis remedies, much more precise observation on the march of events in the infected animal is needed.

Dr. KETTLE points out that two false assumptions appear to underlie much of the evidence which is produced in original papers dealing with this matter: (1) That all guinea-pigs react in the same way to the tubercle bacillus, and (2) that fibrosis or healing of local lesions indicates with certainty the cure of the individual. When the evidence is sifted, as it is by Dr. KETTLE, it is obvious that these assumptions are, indeed, erroneous. In the first place the duration of life in the infected guinea-pig varies very considerably and there is every reason why it should. Probably the path of the infection is not always quite the same in each case, since the inoculating needle in penetrating different planes may cause the dose of tubercle bacilli to get past certain superficial glandular lines of defence. This point has recently been brought to notice in a careful piece of work by Prof. S. LYLE CUMMINS,[1] on the infection of guinea-pigs by the conjunctival instillation of tubercle

[1] Tubercle, January, 1924, p. 153.

bacilli. In this article the writer states that the susceptibility of guinea-pigs to the subcutaneous inoculation of tubercle bacilli is too great to allow of the employment of this form of infection in immunity experiments with virulent strains, and suggests per-conjunctival infection as a more precise method of greater delicacy. If subsequent research be found to bear out Prof. CUMMINS'S observations, it may provide us with at least one possible explanation why subcutaneously infected animals survive for different periods of time even when other factors have, as far as possible, been standardised. Secondary infection is also a possibility which, in our opinion, is not sufficiently allowed for. It is not uncommon to find a tuberculous guinea-pig dying several weeks before its time, whilst the tuberculous lesions are still slight, from what is obviously a secondary infection. Recently an accidental filter-passing infection invalidated a series of experiments on lymphadenoma in rabbits.[2] Again, it is not unlikely that differences in the dietary obtaining in different laboratories at different times of the year, and with varying methods of feeding, may have a bearing on the matter, for it is clear that we are not yet at the end of our troubles with regard to vitamins and infective disease. And yet another possibility must be considered—viz., the hereditary factor in the strain of the animal used. This point appears to have been largely neglected in this country, but a brief reference[3] to it at the eighth annual congress of the National Association for the Prevention of Tuberculosis by Dr. PAUL A. LEWIS, of Philadelphia, who has investigated the question in collaboration with the United States Department of Agriculture, would suggest that the breed is not without influence in regard to susceptibility to infection.

Nor can the weight of the guinea-pig be regarded as an adequate test without further control. Young animals will continue to grow for some time after inoculation with *B. tuberculosis*, and it is not unknown to find such animals heavier at death than at the time of inoculation. For an obvious reason, also, female guinea-pigs should never be used for such experiments, since pregnancy is difficult to diagnose. Individual guinea-pigs differ in their histological response to infection with tubercle bacilli. Palpable glands may diminish in size even in untreated animals, and fibrosis and natural healing may occur in guinea-pigs infected with tubercle bacilli without any form of treatment at all. And finally we have to reckon with the fact that, so far, no one has succeeded in estimating the toxicity of different strains of tubercle bacilli, and that different laboratories are in the habit of using different strains cultivated on media of varying composition. Thus we realise how thorny a path the investigator has chosen who sets out to test an anti-tuberculosis remedy on the guinea-pig. The proposition may be by no means impossible, but there is need of a far more careful standardisation of the conditions of the experiments.

THE LIMITS OF A SURGEON'S LIABILITY.

A SOUTH AFRICAN correspondent referred recently[1] to an action brought by a Miss VAN WYK against Dr. H. LEWIS on the ground of alleged negligence in leaving in her body a swab, after operating on her for certain diseased conditions of gall-bladder. The case was tried at Queenstown by Mr. Justice VAN DER RIET, evidently with great care, and the principal reasons which led him to give judgment in favour of Dr. LEWIS are worth recapitulating. It may first, however, be stated that the fact of the swab having been left in the patient's body by the surgeon when he closed the wound was disputed. The patient's story supported by witnesses was that the wound had discharged and it had otherwise caused her suffering during the year that followed the operation, and that the swab had appeared in a stool passed at her home on Feb. 15th, 1923, the operation having been performed on Feb. 3rd, 1922. After this period of time the defendant and his witnesses, not unnaturally, could not recall details of the counting and checking of swabs on the occasion in question, and could only speak as to the routine usually adopted at the Frontier Hospital, Queenstown, and admit that the checking was done by the theatre sister present, when the patient's condition had rendered urgent the completion of the operation. The defendant and medical witnesses on his behalf were not able to say that the manner in which the swab was stated to have come to light was impossible, but only that it was improbable, and that its appearance did not bear out the plaintiff's story. The theatre sister, however, gave positive evidence that the swab produced was not one that she had ever used, as it was different in size and other respects from those made by her. As to this important point, however, the judge was sufficiently impressed by the manner of the plaintiff in the witness-box, to hold that her story was true and that the theatre sister must be mistaken. His judgment therefore was based upon the fact, found by him as a preliminary, that a swab had been left behind in error, from which it followed that a mistake in checking must have been made by the sister and not discovered by the surgeon, who, as far as he was aware, had removed all the swabs used.

In these circumstances a number of points had next to be considered. In the first place the judge ruled that the leaving behind of a swab was prima facie but not conclusive evidence of negligence. He then had to decide whether a custom or practice had been proved that in operations the theatre sister or other assistant should be responsible for checking the removal of anything under her charge that should be removed before closing the wound. As to this, he held that such an alleged custom need not be shown to be universal. A surgeon charged with negligence was only bound to establish that he employed reasonable skill and care, and from this it followed that if he adopted a system recognised and used by skilful and careful surgeons, which he reasonably considered satisfactory from his experience, it was not necessary to show that it was the most perfect system or one approved by universal practice. As to what had actually taken place the judge was satisfied that, when the operation had been brought to a conclusion after the anæsthetist had called attention to the patient's condition, "the defendant, as far as the exigencies of the case would allow, had made a careful search and was undoubtedly under the impression that he had removed all the swabs." It had been contended that the surgeon had neglected his duty to the plaintiff in not counting or supervising personally the counting of the swabs before, during, or after the operation. After hearing the opinions of many witnesses, he declined to accede to this view, and attached weight to the opinion that to do as was suggested might distract the attention of the surgeon to the patient's detriment. It had been argued that if not personally responsible for the counting, the surgeon was liable for what the sister did, either because she was his "servant" or because he was a "joint tort-feasor" with her. Carefully reviewing their respective positions and duties, he held that in what the sister did she was "a member of a team collaborating with the surgeon"; he would only be liable for her act or omission if it was due to an order or instruction given or omitted by him. He referred in this connexion to the case of Hillyer v. the Governors of St. Bartholomew's Hospital,[2] and to the earlier case of Perionowski v. Freeman[3] decided by Chief

[1] THE LANCET, Jan. 5th, p. 47.

[3] 4 F. and F., p. 977.

Justice COCKBURN in 1866, as well as to "Beven on Negligence."[4] The defendant and the sister could not be held to be joint tort-feasors, as they could not in any way be said to have been jointly engaged in any wrongful act.

It will be seen from the above summary that the case, like others of its character, offered many difficult points for consideration, and Dr. LEWIS is to be congratulated upon having successfully defended himself against a serious charge of negligence, arising out of an accident such as only occurs because, in the words of Judge VAN DER RIET, "no system has yet been devised by which the element of human fallibility can be eliminated." He was also perhaps fortunate in that his case was tried by a judge in accordance with the law and with good sense, and that the element of sympathy that sometimes affects the verdict of a jury and makes for injustice was thus eliminated. As it was, a bitter attack on the conclusion arrived at is quoted from a Bloemfontein newspaper in the *South African Medical Record*, and answered with the vigour it deserves by our contemporary. It includes the statement that "the fact that a medical practitioner cannot be held legally responsible for such an occurrence will be read with amazement by common people." This, of course, is untrue, for the judge expressly laid down in his judgment, quoting from "Beven on Negligence," that leaving a sponge or an instrument in a patient after an operation is prima facie negligence, but that the fact that it is so left is not conclusive. "The conclusion from the fact must be determined by a jury on a view of the whole circumstances." The public, from which juries are drawn, should realise that in the thousands of operations which take place annually the most anxious care is exercised by the surgeon, and by those who assist him, to prevent any occurrence such as Judge VAN DER RIET found took place in the case before him.

THE PSYCHOLOGY OF ÉMILE COUÉ.

DURING his visits to this country Mr. Coué found both admirers and scoffers but few hostile critics. In the current *English Review* an American writer, Dr. Emil Axel Gibson, makes a vigorous attack upon his methods and, pointing out their connexion with hypnotism, sketches their dangers with a heavy pencil. To Dr. Gibson the "will" of the hypnotist is an entity that can enter the mind of another and do strange things therein, and by the power of his will the mental healer can play upon the moral, mental, and physiological consciousness of his subject, as an electrician, by connecting his wires with the batteries of his system, can light every lamp or sound every bell within the ramifications of the connecting lines. A hint of mysterious power lies in the information that in cataleptic disorders "an association with outside mental control over the freedom of will cannot be doubted." This points to bewitchery and prepares us for the conclusion that "the situation is grave enough to call for a warning against practices which may lead to the greatest tragedy that can happen to human nature—the collapse of individuality and the debasement of will." But the danger is not so great as Dr. Gibson fears. Medical psychologists show no signs of being perturbed by the popularity of Mr. Coué, an enthusiast whose charming and paternal manner arouses in his subjects a feeling of delightful dependence that enables them to put aside their neurotic troubles. Perhaps his cures are neither complete nor lasting, but neither he nor any other mental healer possesses the malign powers ascribed to him by Dr. Gibson.

[4] Third edition, p. 1161.

WE regret to announce the death, at Exeter, on Jan. 11th, of Mr. Arthur Charles Roper, oculist and hon. consulting surgeon to the Royal Devon and Exeter Hospital. He was in his sixty-sixth year.

Annotations.

"Ne quid nimis."

THE GENESIS OF GALL-STONES.

PATHOLOGISTS to whom text-book orthodoxy is anathema will read with much interest a paper on the genesis of gall-stones, published in German, by Prof. T. Rovsing, of Copenhagen, in *Acta Chirurgica Scandinavica* (Vol. LVI., Fasc. 2 and 3, pp. 103 and 207). For the past 30 years he has been systematically collecting material wherewith to refute the teaching of Naunyn and others that a gall-bladder must be infected before stones can develop in it. In this period 530 cases of gall-stones were operated on, and in every case a bacteriological examination was made under aseptic precautions at the time of operation. In some cases the bacteriological examination of the contents of the gall-bladder was supplemented by a microscopic examination of a section of its walls and by a bacteriological examination of the interior of the gall-stones. It was found that the contents of the gall-bladder were sterile in 314 cases and infected in 216. In no case in which the bile was sterile could germs be found within the gall-stones, and in only one of the 530 cases was it impossible to demonstrate a core of pigment in the stones. The youngest patient was a child, barely one and a half years old. In this case the bile was sterile, and the common bile-duct was obstructed by a quantity of coal-black grit. There was no sign of any inflammatory reaction, and Prof. Rovsing suggests that this early case gives a valuable clue to the genesis of all gall-stones.

As a result of this prolonged study Prof. Rovsing is inclined to believe that gall-stones all begin as a small nucleus of pigment which forms the core of the stone. Sepsis is, in his opinion, a sequel, not a cause, and he dismisses as untenable the ingenious suggestion that an infected gall-bladder may become sterile after the development of a stone, the germs supposed to be responsible for this development slipping unobtrusively away after the mischief was done. His argument in opposition to this teaching hinges on an analogy. In no case of calculus of the bladder with infection of the urine has sterility been achieved without removal of the calculus. It is, therefore, improbable that a septic gall-bladder should automatically become sterile so long as it harbours a gall-stone. Sepsis should therefore be regarded as a sequel—a very serious sequel—to the development of gall-stones, and not as a cause thereof. Prof. Rovsing ridicules the notion that facets are produced on gall-stones by their pressing on each other under the spasmodic clutch of the gall-bladder. Facets, he suggests, are the expression of the intrinsic properties of the constituents of certain gall-stones, and he notes that in the urinary bladder the oxalate stone is spherical, while the urate stone is a flat oval. He has also noticed that when gall-stones are multiple, they are usually of the same size, and that it is very rare for more than two or three different sizes to be found in the same bladder even when it contains many hundred stones. This observation suggests that all the stones of the same size found in a gall-bladder were formed at the same time, and Prof. Rovsing believes that the period during which a crop of gall-stones is created must be quite short. He suggests that the core of a gall-stone is always, or nearly always, formed in the intra-hepatic biliary passages by the precipitation of black pigment chalk, the process being determined by a transitory "diathesis" comparable with the periodic precipitation of uric acid, uric acid salts, and calcium oxalate in the kidneys.

Two other observations deserve special mention. It has been suggested that ptosis of the viscera, notably the liver and stomach, favours the development of gall-stones by obstructing the biliary passages. Among the 300 cases operated on for gastro-coloptosis by Prof. Rovsing during the past

25 years, there were only eight in which gall-stones were found at the time of operation. Further, among the 530 patients operated on for gall-stones, there were only 18 women and one man suffering from gastro-coloptosis. The poor state of general nutrition of ptotic patients may give a clue to their comparative immunity from gall-stones, which are most common in fat persons. The other observation is also instructive. Among 30 cases of chronic biliary obstruction and jaundice coming to operation, and 32 coming to necropsy, there was not one showing the slightest evidence of gall-stones, whether the chronic jaundice was associated with sepsis or not. In other words, prolonged biliary stasis with jaundice does not evidently promote the development of gall-stones.

LEPROSY IN PARIS.

THE danger of leprosy spreading in Paris is by no means negligible at the present time, for at least 200 lepers have drifted there from foreign countries. Prof. M. E. Jeanselme recently demonstrated to the Academy of Medicine [1] a case of macular leprosy in a young man of 16 years who had contracted the disease in Paris. The patient was born in that city, where he had resided all his life. His father, an ex-marine, had served abroad in Guiana and Cochin China, and in 1913 developed leprosy—that is, eight years after his return from abroad. The mother of the leprous youth remains perfectly healthy. There can be no question in this case of hereditary transmission of the disease, for at the time of the birth of his son the father was perfectly healthy; on the other hand, it is probable that the disease was transmitted from father to son by actual intimate contact. The author points out that in the Hospital Saint Louis, where lepers have been segregated in one room for very many years, no case of contact infection has so far been recorded, but here is an infection contracted in the family circle in a spot far removed from any endemic focus of the disease. Unfortunately this is by no means a unique case of contact infection by leprosy in Paris; at least three similar cases have been recorded since 1885. In view of this evidence, Jeanselme urges the Permanent Leprosy Commission to study anew the prophylactic measures to prevent the spread of leprosy in France.

THE NERVOUS COMPLICATIONS OF PARATYPHOID FEVER.

ACCORDING to Dr. G. Artom,[1] assistant at the Clinic of Nervous and Mental Diseases of Rome, who records an illustrative case, nervous complications apart from meningeal involvement are uncommon in paratyphoid fever. Schottmüller reported a case of epileptiform attacks in a girl, aged 20, who had not previously suffered from epilepsy, but was of an irritable and eccentric disposition. Cases of tetany have been recorded by Bedos, Babonneix, Corone, Bossert, and Vincent and Muratet. Examples of hemiplegia have been related by Cestan, Descomps, Euzière, and Sacage who attribute it to cerebral arteritis. Schürer has described a case of dysarthria, which he attributed to hæmorrhagic inflammation of the bulbar nuclei, and Etienne has reported a case of permanent spastic paraplegia. Bingel has published a case of spastic paresis of the limbs without involvement of the facial nerve, and regarded the condition as due to acute encephalitis, and Goston and Schett have related a case of cerebral abscess in paratyphoid B infection. Dr. Artom's case was in a neuropathic female infant, aged 13 months, who developed paratyphoid B fever, accompanied by psychical disturbance in the form of alternate drowsiness and restlessness. The restlessness disappeared, but the drowsiness became more pronounced, and severe nervous symptoms developed in the form of conjugate deviation of the head and eyes to the right, slight nuchal rigidity, and generalised clonic movements. Lumbar puncture gave issue to an abundant clear fluid containing a slight excess of albumin and lymphocytes, with a few polymorphonuclear cells. The clonic movements and nuchal rigidity disappeared in a few days, and spastic left hemiplegia developed. This condition lasted until the temperature became normal on the twenty-ninth day of disease when rapid improvement began, and in another fortnight complete recovery took place. The symptoms in this case were probably due to a toxic impregnation of the cerebral cells and meninges, possibly accompanied by slight vascular infiltration and œdema. Severe vascular lesions, such as arteritis, thrombosis, or hæmorrhage, were excluded by Dr. Artoun, as they could not have cleared up so quickly.

FOOD AND DISEASE IN THE TROPICS.

DURING his long service in the Navy Sir P. W. Bassett-Smith had constantly to deal with the practical application of dietetic principles and the fruits of his experience are manifest in an address which has now been reprinted.[1] Just as in civil life the ultimate result of a deficient dietary is to produce civil disobedience and political unrest, so, in former times, bad rations fomented open mutiny in the Navy, as in the reign of George III. In the tropics the maintenance of a balance between the intake and output of heat should be the main consideration underlying the dietary, so that the ration supplied to naval ratings in the Persian Gulf has to be based upon a different scale from that supplied in more temperate climes. The value of protein in the dietary should depend largely upon the amount and kind of amino-acids which it contains, two only of which—tryptophane and lysine—appear to be indispensable for life. The greater the similarity of the protein supplied to the tissues, the higher is its value; hence the biological protein value of meat and milk is three to four times as great as that of maize. In the tropics people tend to rely more particularly upon one kind of food—e.g., rice, maize, bananas, manioc, figs, or dates—for the maintenance of life, and this very dependence on one particular product tends to produce, in times of scarcity, malnutrition and susceptibility to disease. The lecturer showed how the dietaries of the several navies when compared showed considerable variations, those of the United States giving the highest caloric value, the French and Japanese showing much lower fat values than those of the British and Americans, more in conformity with tropical conditions. Tropical heat has a depressing action upon many physiological processes, lessening the respiration rate, and with it the absorption of oxygen and the excretion of carbonic acid, resulting in retention within the body of CO_2 with production of glycosuria and acidosis. In addition to the basic supply of protein, fats, carbohydrates, and salts, accessory food substances—the vitamins—or "food hormones" are essential to health. Sir P. W. Bassett-Smith concluded by directing attention to the experiments on guinea-pigs which showed that animals fed on a diet rich in vitamins, such as marmite, exhibited an enhanced resistance to tuberculous infection as compared with a control series fed on a normal dietary.

RECURRENT ATTACKS OF INFANTILE PARALYSIS.

THE germ of infantile paralysis is generally supposed to confer immunity to a second attack. Attempts have often been made to reinfect monkeys which have contracted experimental infantile paralysis, but these attempts have always failed. The reason for this failure is probably to be found in the researches

Levaditi, Flexner, and Lewis, who have demonstrated in the blood of persons recovering from this disease substances capable of neutralising its virus. During the epidemic of 1916 in New York two cases were, however, reported, in which more than one attack occurred in the same patient. In *Le Scalpel* for Nov. 17th, 1923, Dr. Gaston Peremans has recorded a case in which the disease recurred in three successive waves. The patient was a girl aged 4 years and 9 months. On her admission to a children's hospital in Boston, U.S.A., in July, 1920, there was a history of drowsiness and morning vomiting for the past six weeks. The vomiting had become more severe during the past 15 days, and during the last week there had been attacks of convulsions, the first of which had lasted one or two minutes, the second 20 minutes. Since then she had been very weak, groaning when she raised her hands to her head. In hospital she cried when she was touched, the reaction of the pupils was very slow, there was slight cervical rigidity, and Kernig's sign was positive on both sides. The preliminary diagnosis of tuberculous meningitis was unsupported by the evidence of lumbar puncture, and she was discharged from hospital with the diagnosis of anterior poliomyelitis. She was re-admitted to hospital in October, 1920, with the history that for three months she had been well in spite of morning vomiting accompanied by abdominal pain and drowsiness. Eight days before admission to hospital incessant biliary vomiting began, and she complained of pain in the left lumbar region and the right half of the head. Four days later she could not move her limbs, and she screamed when her head was touched. Passive movements of the legs were painful, and the left leg showed a flaccid paralysis. The left arm was weak, and the movements of the left side of the chest were less ample than those of the right side. Pirquet's reaction was negative, and no tubercle bacilli could be found in the cerebro-spinal fluid. About two years later a third attack occurred, being characterised by anorexia, vomiting, and pain. It was less severe than the previous attacks, and on this occasion areas which had been almost intact were involved. The arms were painful, and the wrists assumed a position of permanent flexion. Slight atrophy of the dorsal muscles of the hands developed. Re-examination of the cerebro-spinal fluid failed to show any sign of a tumour of the cord. Dr. Peremans suggests that the immunity conferred by the first attack must have been so transitory that reinfection occurred.

BLOOD URIC ACID IN SKIN DISEASES.

AT the last meeting of the American Dermatological Association Dr. Jay Frank Schamberg, director, and Mr. Herman Brown,[1] chemist of the Research Institute of Cutaneous Medicine, Philadelphia, read a paper on the blood uric acid in diseases of the skin with particular reference to eczema and pruritus, based on the analysis of the blood of 280 persons. They remark that there has been a tendency on the part of American writers on dermatology to pay little or no attention to the relationship of gout and eczema, which has always been emphasised by French dermatologists and to some extent by specialists in this country, especially Tilbury Fox. Although there is no unanimity at present as to what constitutes the maximum normal for uric acid in the blood, the writers are of opinion that it is about 3·7 mg. per 100 c.cm. of blood, estimated by which standard 44 per cent. of their 161 cases of eczema and 50 per cent. of 10 cases of pruritus showed an excess of uric acid in the blood. The type of eczema in the main associated with excess of blood uric acid was the erythematous form, although the vesicular and other types were represented. On the other hand, in psoriasis, urticaria, acne rosacea, acne, and other cutaneous diseases the percentage of cases of hyperuricacidæmia was strikingly less than in eczema. Age appeared to exercise a considerable influence on the quantity of uric acid in the blood. The highest uric acid values were found between the ages of 40 and 80, and decidedly lower rates were observed between 15 and 40. The rise in uric acid, however, as age advanced, was much more obvious in patients with eczema than among those with non-eczematous dermatoses. The influence of sex was shown by the fact that the average amount of uric acid in the blood was 3·6 per 100 c.cm. among 167 male patients as compared with an average of 2·7 mg. among 140 female patients; among eczematous subjects the average of 95 male patients was 3·9 mg., and of 69 female patients 3 mg. In several cases the writers made a determination of the uric acid in the scales thrown off the skin. While the method was less accurate than the determination of blood uric acid, the results were suggestive. There appeared to be a relationship between the blood content and the scale content, but the amount of uric acid in the scales was higher. Patients with an excess of blood uric acid were placed on a diet from which meat, fish, fowl, internal organs, and meat soup were excluded. Eggs and milk were allowed, as they yielded no purin products. On the whole, the results were very gratifying, though in some instances dietetic treatment was disappointing.

COMBINING RADIUM EMANATIONS WITH FAT.

Prof. J. Strasburger,[1] of Frankfurt, reports the results of experiments to increase the availability of radium emanations by using fat as the vehicle of transport instead of water. He has previously published several articles showing that the effect on the tissues of the body increases with the increase in the quantity of radium emanations introduced, but unfortunately the quantity of radium available is generally too small to allow of the use of such large doses, and therefore he seeks to find a way of increasing the availability of the radium without increasing the dose. Radium emanation is, as is known, a gas, which can be dissolved in water, and which is readily given off from the latter into the air, where it diffuses. Introduced into the body it diffuses through the lung capillaries into the expired air. Chemically the emanation is combined neither inside nor outside the body as "Edelgas." Prof. Strasburger's idea is to make a stronger physical combination with the emanation than has hitherto been done in order to retain it longer in the body, and so make its availability greater. He gives the coefficient of solubility of emanations in air and water (given equal volumes of both, and taking the coefficient of air = 1·0) as water at 20° C. = 0·25; water at 30° C. = 0·20; water at 40° C. = 0·16. Various paraffins and fats dissolve more radium—e.g., vaseline will dissolve nine times as much radium as air, and therefore 36 times as much as water at room temperature, while olive oil dissolves 28 times as much as air or 112 times as much as water. These facts have been made use of by Prof. Strasburger both for external application and for internal administration.

For External Application.—In baths containing emanations it is only the thin layer covering the skin that has any action, for the α rays penetrate only to a depth of 1/10 mm. and the β rays only to a few centimetres. Prof. Strasburger therefore recommended that the action might be strengthened by substituting for the baths packs of emanation water, enveloped in an airtight covering, to prevent the diffusion of the emanations into the air, but even so the emanations very rapidly diffused off. He found that by dissolving the emanations in vaseline and applying it in the form of an ointment to the skin the rate of diffusion into the air was very much diminished. The difference between water and fat solutions when free access to the air is allowed is shown by a graph. The thickness of the enveloping sheet of emanation-containing substance naturally influences the rate of diffusion. Whereas with a thickness of 15 mm. of water 55 per cent. of the emanations are present after 15 minutes, in vaseline of the same thickness 90 per cent. are still present at the end of an hour, and with a thickness of 2 mm. only 20 per cent. are retained in water after the

[1] Deutsche med. Wochenschrift, Nov. 30th, 1923.

first minute, while 38 per cent. remain in vaseline after an hour. If the air is cut off by an airtight covering, the concentration available for therapeutic use is still further increased. A solution of emanations in fat produces in another way a greater therapeutic effect than a solution in water; for while it is true that with water packs or baths the emanations diffuse to a certain extent into the body and are given off in the expired air, this action is very limited, as the water remains on the surface of the skin and only very slightly penetrates into the pores. On the other hand, the ointment penetrates through the sweat pores and hair follicles deeply into the corium, and the epidermic cells themselves take up the fat (as can be demonstrated by the fact that many substances can be found in the urine after applying them to the skin). Therefore even when the layer of ointment is removed from the surface, a certain amount remains behind, and the action of the emanations continues for some hours. One may assume that the emanations reach the nerve-endings, and by virtue of their lipoid solubility may be retained and stored in the nerve sheaths. It is also possible that they may travel (similarly to tetanus toxins) along the sheaths to the central nervous system. In this way Prof. Strasburger explains the effect on trigeminal neuralgia of emanation ointment applied to the face. He has used this application with increasing success in such cases, and finds that the pain is relieved after daily application continued for a few days up to two to three weeks, suggesting that the time taken may be necessary for the emanations to travel up the nerve sheaths to the Gasserian ganglion.

Internal Administration.—If a watery solution of emanations is taken by the mouth the emanations pass into the portal system and into the right ventricle. While passing through the lung capillaries most of the emanations are given off into the alveolar air, and only a very few reach the systemic circulation. If the solution is taken on an empty stomach the expired emanations reach a maximum in a few minutes, then sink, first rapidly, and later more slowly, until in about 50 minutes no more are given off. When taken on a full stomach, the quantity of expired emanations does not reach such a high point, but remains for a longer time at a medium height and only sinks slowly till zero is reached in about two and a half hours.[2] Thus in the first case an intensive action of short duration is present, while in the second a weaker action of longer duration is obtained, and this, in considering the therapeutic effect, is an important point. If the therapeutic value is required not only of the α rays, which come off first, but also of their breakdown products, the β and γ rays, which are found later, then it is clear that it is of the utmost importance to retain the emanations in the body for as long as possible, and in this direction Prof. Strasburger has conducted his experiments. With his co-workers, Dr. Vaternahm[3] and Dr. Möhrle, he has shown that if an olive oil solution is taken internally, the emanations are retained in the body for a longer time than when a watery solution is used. This is true with an empty stomach, and still more so with a full one. With oil taken on a full stomach it is over six hours before the expired air is free from emanations. This phenomenon may be explained as follows: (1) fat leaves the stomach more slowly than water, and therefore absorption from the intestine is delayed; (2) in virtue of their high solubility in fat, the emanations are only slowly given off in the intestines to the surrounding fluid; the rate at which the emanations are absorbed from the intestines depends upon their solubility in the products of fat digestion—namely, fatty acids and soaps; for if their solubility in the latter substances is less than in neutral fats, then a proportion will be set free and will rapidly diffuse into the tissues, while that quantity of emanations which are soluble in fatty acids and soaps will remain dissolved for a time proportionate to the coefficient of solubility for these substances. Experiments are still being carried out to determine this coefficient, but it has already been shown that the coefficient for fatty acid is approximately the same as that for neutral fats, while that for soap is considerably higher than that for water.

All the foregoing facts taken together point to an increase in the absorption time as compared with water. But is the increase in the time of the expiration of the emanations into the air accounted for alone by the increase in the absorption time? The problem of retaining the emanations in the body has been half solved by Prof. Strasburger by increasing their solubility, and he has thus succeeded in retaining them longer during their transit from the mouth to the intestine and during their absorption into the blood, but the next question is more difficult—that is, whether after absorption into the blood, the physical combination with fat has any further effect and can carry them past the lung capillaries (where most is expired) into the systemic circulation in greater quantity than is otherwise the case, for it is only those emanations that have passed through the lungs that reach the joints, muscles, nerves, connective tissue, &c.—in short, those places where their healing powers are needed. The answer to this question can be approached in several ways. We can follow in imagination the emanations, dissolved in oil, passing from the intestine into the thoracic duct and so into the venous blood-stream, the quantity of the blood depending on the fat content of the latter, and consequently increasing after a meal, more especially if such be rich in fats. The emanations then pass through the capillaries of the lungs, where most is given off into the alveolar air—but not all. That this is so is demonstrated by experimental estimation of the total quantity of emanations given off in the expired air. Such estimations have been carried out, and Prof. Strasburger has also, in order to eliminate any loss of emanations during their passage from the mouth to the intestine, introduced them direct into the duodenum. The result of these experiments shows that of 3000 M.E. (Maché units) in water, 69 per cent. are recoverable in the expired air, while from the same quantity dissolved in 20 c.cm. olive oil 56 per cent. are expired. Thus the quantity retained in the body and otherwise transformed or excreted is 31 per cent. and 44 per cent. respectively.

Further experiments consisted in injecting a fine emulsion of emanation-containing oil into a vein and measuring the expired emanations. A graph shows the quantity expired during the first minute, using water and varying quantities of oil, and indicates that the greater the quantity of fat introduced the less the amount of emanations expired. Experiments with much larger quantities of oil up to 250 c.cm. are still in progress. The last link to be discovered is the quantity of emanations present in the arterial blood, and investigations on this point are being undertaken. The conclusions that Prof. Strasburger draws from his work are: that it is possible to bring a larger quantity of radium into action, not only by increasing the dose, but by increasing the availability of the emanations; and that this object is attained by taking advantage of the fact that emanations are more soluble in fat than in water.

WORKMEN'S COMPENSATION IN 1922.

REMARKABLE figures as to miners' nystagmus are a feature of the Home Office statistics [1] of compensation and proceedings under the Workmen's Compensation Act of 1906, and the Employers' Liability Act, 1880, for the year 1922, just issued. In the figures of industrial diseases, cases of miners' nystagmus amount to 68 per cent. of the total number. This disease was first scheduled in May, 1907, under Section 8 of the 1906 Act. Figures for the years from 1908 to 1922 are now available. In 1908 386 new cases were recorded. The total climbed over the 1000 mark in 1911, and passed the 2000 mark in 1913. In 1914 there were 2775 new cases; in 1919 and 1920 this figure was but slightly varied. The three months' stoppage in the mining industry in 1921 may have been a reason why the total of new cases sank to under 2000 in that year. In 1922, however, the figure has made a startling jump up to 4092.

Other points of general interest in the report are the statistics illustrating the increasing recourse to the services of medical referees. There is power under Article 15 of Schedule II. of the 1906 Act for committees, arbitrators, and judges to refer cases to medical referees. In 1922 208 cases were thus referred in England, and 80 in Scotland. Under Article 5 of the same schedule (which has since been altered by the 1923 Act) a county court judge can summon a medical referee to sit with him as assessor. This was done in 465 cases in 1922. Under Article 15 of Schedule I. recourse is had to medical referees (by

[1] Cmd. 2007. H.M. Stationery Office. 1923. 6*d*.

agreement between the parties) for certificates of the condition of the workman and of his fitness for employment, or for decision whether and how far his incapacity is due to the accident. This was done in 1224 cases in 1922 as against 655 cases in 1921. Finally, under Section 8 (1) (*f*) of the 1906 Act there is an appeal to medical referees against the decision of a certifying or other surgeon in giving or withholding a certificate of disablement on account of industrial disease. There were 1049 such appeals in 1922 as against only 479 in the previous year. It is perhaps worth noting that in as many as 387 out of the 1049 appeals the surgeon's decision seems to have been overruled. The annual statistics relating to medical referees will be affected in future years by the new provisions of the 1923 Act and by the various new regulations made on Dec. 17th of last year.

Two other matters of interest are the decrease in litigation under the Acts and the slight increase in the proportion between payment of compensation and cost of insurance. As is well known, there are many who advocate as a political measure the handing over to the State of all insurance against workmen's compensation and employers' liability. They point, on the one hand, to the low figure of administrative cost in countries where the State has undertaken the monopoly of its own insurance system. On the other hand, they show that where such insurance is left to private enterprise, the insurance companies have to spend (in competition with one another) so much money on offices, advertising, canvassers, and so on, that a considerable sum is wasted upon overhead costs which might otherwise be given to increased benefits. The position in 1922 shows some improvement here. In 1921 the proportion of income allocated to payment of compensation by insurance companies was only 35·95 per cent. In 1922 it was 44·46. In future years the proportion will be higher still, the big accident insurance companies having entered into a self-denying arrangement with the Home Office that the figure shall be not less than 60 per cent. in future, with the possibility of still further improvement.

A HEALTH SURVEY OF A CHICAGO PRISON.

THE American system of health surveys is proving its utility, throwing rays of light into many a dark corner. The Chicago Bridewell would seem, from a report [1] of one of these health surveys, to be a dark corner indeed. The survey was initiated by the Municipal Tuberculosis Sanitarium. Altogether 1181 inmates were examined, 784 being stripped and exhaustively examined for non-tuberculous as well as tuberculous conditions. The ratio of whites to blacks was as 70 to 30, and 136, or 11·5 per cent. of the total, were found to be tuberculous. In 79 other cases there were uncertain signs of tuberculosis, and only 966, or 81·9 per cent., could be regarded as non-tuberculous. Dental caries was found in 675 cases, and pyorrhœa in 400. The examining physicians reported that the mouth condition in this class was the worst they had ever seen. The great majority of the prisoners had from two to eight old rotting stumps, often associated with pyorrhœa and inflamed or ulcerated gums. Obviously the dental service at this institution was inadequate, and it is urged by the examiners that the opportunities neglected in this prison must sooner or later be paid for by a large crop of destitute invalids suffering from chronic rheumatism and heart disease for which the community must pay for an indefinite period. "It is cheaper," they remark, "to pay one full-time dentist now than to support hundreds of incurables a few years from now." Five hundred of the prisoners suffered from chronic pharyngitis, and 20 from hernia. The most representative criminal in this prison was the petty thief or pickpocket, whose small, under-nourished, anæmic frame obviously rendered him incapable of doing a day's physical work even had his cravings pointed in that direction. "It seems probable that an individual of this type is, in many instances, a pickpocket from necessity rather from choice. . . . He must thieve or he must starve." The report on the general hygiene of the prison is a damning indictment. "They are not taught hygiene, and they do not live hygiene. They are locked in their cells at 4.30 in the afternoon and remain locked up till 6 or 7 next morning. Of the 1600 inmates, 1000 live in cells, often two to a cell, in which there are no toilet facilities. Two-gallon cans without covers are supplied in lieu of toilets. The physical discomfort and moral degradation of this arrangement, even to those whose sense of common decency is far from keen, may well be imagined. It is only fair to state that the superintendent of the institution has tried for years to secure better health conditions at the Bridewell, but without avail." There is much more to the same effect in this stinging indictment of a state of affairs which carries us back to the barbarism of the Middle Ages. Incidentally this report shows how difficult it may be to carry reforms from within, however anxiously the officials of certain institutions desire them.

[1] Bulletin, City of Chicago Municipal Sanitarium, Nov. 1923.

BLOOD GROUPS AND OPSONINS.

THE excessive number of variables which come into play in the opsonic technique has, for a majority of workers, proved a fatal obstacle to the gathering of useful information from the determination of opsonic indices. In a short paper, which we publish in our present issue, Dr. F. C. Martley has drawn attention to yet another complicating influence. He has found that under similar conditions, in the case of an individual belonging to blood group ii., the corpuscles appear to be more active in phagocyting tubercle bacilli than those of individuals of two of the other blood groups —viz., iv. and iii. Making a larger series of experiments with a number of individuals, he finds that an increased phagocytic ability is apparently inherent in the leucocytes of persons belonging to group ii. These observations are interesting and worthy of a more extended investigation. It also appears to us that, from his initial experiment, Dr. Martley might equally reasonably argue that with the same corpuscles a group ii. serum seems to be more active in exciting phagocytosis than that of the other groups, and that the serum factor is deserving of investigation as well as the corpuscular one; in this respect the influence of agglut nation may come in. It might be expected that where corpuscles are in the presence of a serum which contains iso-agglutinins for the group to which they belong, that marked differences of opsonic power would be noticed relative to what occurs between homologous serum and corpuscles from surface alteration of the corpuscles, but in the single experiment in which one can search for evidence upon this point we find no such variation. The investigation is an interesting one, and points out an as yet unconsidered factor to be reckoned with in opsonic determinations.

THE PRACTICE OF MEDICAL GYMNASTICS.

Two addresses recently delivered to the Chartered Society of Massage and Medical Gymnastics emphasise the intimate relation in which this branch of practice stands to medicine. Dr. J. B. Mennell's lecture appears substantially in full on another page; the time now seems remote when, as he reminds us, a deputation of his fellow house officers waited upon him to request him not to degrade his profession by studying such a doubtful branch of medical practice. During the 15 years which have elapsed since then, Dr. Mennell has learnt many things, to do and not to do: among them, that it is far easier to rub a disability into a patient's mind than it is to rub it out of his limb; and, on the other hand, that in every joint, with the solitary exception of the hip-joint, it is possible for the gymnast to perform some movement not ordinarily under the patient's voluntary control. Sir William Milligan's "Founders" Lecture,

delivered last Monday to the Society, opened with an interesting historical summary of medical rubbing from the earliest times. He recalled the aphorism of Hippocrates that "soft rubbing loosens; much rubbing causes parts to waste; moderate rubbing makes them grow." The competent masseur of to-day is not only a trained manipulator and rubber, but has become also a physico-therapist and to some extent a psycho-therapist, with the art of imparting hope and encouragement to his patients. So long as the present excellent and comprehensive training is insisted upon and so long as no extravagant claims are made, Sir William Milligan regards as certain the medical gymnast's hold on the respect of the medical profession and the gratitude of the public. In orthopædic surgery the best end-results can hardly be obtained without recourse to mechano-therapy; effleurage is now begun almost at once in the case of that very common injury, a sprained ankle; massage soothes in some degree the dreadful paroxysms of pain in tic douloureux. Turning to his special department, Sir William Milligan laid stress on the need for instituting massage in middle-ear disease the moment facial paralysis or weakness becomes apparent, for the facial musculature is peculiarly prone to rapid degenerative change; in the condition known as boxer's or footballer's ear, immediate massage may avoid the deformity, so likely otherwise to be permanent. In building up the muscle tonus in general, the masseur is thereby increasing the effort and endurance of the heart itself. Without thorough grounding in anatomy and physiology, however, he can hardly set out to correct the many postural defects which are the result of faulty bodily mechanics. In conclusion, Sir William Milligan emphasised again the long and careful preliminary training required for proper appreciation of the therapeutic value of massage and physical exercises.

DR. ALBERT ABRAMS.

THE death is announced from San Francisco of Dr. Abrams, whose name was in recent years associated with so-called electrotonic reactions. He was born there in 1863, graduated in medicine at Heidelberg in 1882, and after further study in London, Berlin, Vienna, and Paris returned to San Francisco, where he became professor of pathology at the Cooper Medical College and in 1904 president of the Emanuel Polyclinic. At this period of his life Dr. Abrams was a prolific writer on clinical topics, his published works including a Manual of Clinical Diagnosis (1894), Transactions of the Antiseptic Club (1896), Nervous Breakdown (1901), and Spinal Therapeutics (1909). He then took up the subject of spondylotherapy, and presided over an association for its study. His electro-tonic work developed into an elaborate system of diagnosis and treatment which was considered by scientific medicine to be devoid of any basis, and on this point considerable evidence is now forthcoming. A correspondent of THE LANCET, recently travelling in the United States, has prepared a report for our columns, which will appear shortly. The necessity for publication is felt particularly by medical men in the United States, where the theories of Dr. Abrams appear to have obtained some hold, largely owing to the credulity of prominent laymen.

WE learn that Dr. D. E. Derry, professor of anatomy at the Government Medical School in Cairo and a well-known anthropologist, has been charged with the examination of the mummy of Tut-Ankh-Amen, and that Sir Archibald Reid's coöperation will be available for the X ray technique. Calcified ova of bilharzia have before now been found in mummified kidneys, and calcification of the arteries seems to have been one of the commonest of diseases in the time of the Pharaohs, affecting both young and old. What else the examination may reveal is a matter for intelligent speculation, but nothing is likely to miss the combined efforts of anatomist, anthropologist, and radiologist.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

LIV.—TREATMENT OF THE ACUTE MENTAL CASE.[1]

ACUTE DEPRESSION AND ACUTE EXCITEMENT.

Acute Depression.

A CONSIDERABLE degree of depression may have existed unrecognised or misdiagnosed before the acute phase of the condition makes the diagnosis of "melancholia" clear. The management of a case of melancholia is a very large and sometimes a complicated question, but the immediate home treatment, which is largely symptomatic, is clear enough in certain important respects, and must be instituted without delay. By far the most important point is the fact that probably all acutely depressed patients have suicidal impulses at one time or another during the illness, and many have them constantly. There is only one safe rule in this matter: *Never* allow the patient to be out of the sight and immediate care of some responsible person. Neglect of this rule will sooner or later result in that greatest of tragedies, the needless death of a recoverable case. Inasmuch as the majority of suicides occur in apparently convalescent cases, the practitioner will be well advised never to relax this precaution, which should be taken the moment melancholia is suspected, without obtaining a second opinion. Commonsense measures, such as having the patient's rooms on the ground floor, removing sharp knives, knitting-needles, door keys and the like will suggest themselves and are important. Many a patient has committed suicide at leisure behind the locked door of a bathroom or water-closet, the attendant having acceded to the patient's plausibly expressed desire for privacy. A discussion of the question of suicide with the patient is perfectly good practice, and is often of great help in making the position clear. The view that, by doing this, one "puts the idea into the patient's head" is entirely fallacious.

Finally, it may be said that the vast majority of melancholics are honest with their physician and themselves, in the sense that when they say definitely and unequivocally that they are now well and have no intention of attempting suicide, they are to be believed. A convalescent patient who only goes the length of saying he thinks he ought to be all right now, or words to that effect, should in general be regarded as still very far from well. Next to the preventing of suicide, the cardinal points in the treatment of acute depression are: rest in bed (in the open air if possible), attention to the gastro-intestinal tract, which is invariably disordered, treatment of the sleeplessness, which is a constant feature, and relief of the patient's bodily restlessness and mental suffering. Physical improvement precedes mental, and the variations in body-weight make an excellent index of progress.

Opium has long been recommended as the best physical and mental calmative, and Battley's solution is a favourite form for its administration, but it is doubtful if it has any great effect in most cases, unless pushed to unwisely large narcotising doses. Calcium salts have been much tried and praised of late years, and some believe that very small doses of sulphonal (5 gr. twice daily) are of use in taking the edge off acute depression. The results are usually disappointing whatever drug is used. For actual sleeplessness, paraldehyde is best and may be given in doses of from 2 to 4 drachms the very last thing at night. As its effects are apt to wear off in the early morning, in a really sleepless case it may advantageously be given along with some drug which is

[1] An article on the treatment of Acute Delirium appeared in the last issue of THE LANCET.

slower but more sustained in its action. Seven to ten grain doses of veronal are much used for this purpose. Constipation is usually most troublesome to combat, and refusal of food as the result of various delusions, or as an attempt at suicide by starvation is unfortunately only too common. Even commoner is a process of slow starvation due to the patient eating something, but not nearly enough, at every meal. Tube feeding must be resorted to without undue delay, and the patient rarely raises any great objection.

Reassurance rather than argument is the keynote of correct dealing with the patient's mental distress. His fears and delusions did not arise out of, nor will they be removed by, any process of logic. While occupation and interest are the patient's great mental needs, yet the process of "rousing" and "cheering him up" is often much overdone. Inability to respond to emotional stimuli is of the very essence of the patient's illness. For this reason, too, unwillingness to "add to the patient's depression" by telling him, for example, any bad family news during his illness is needless. Such news will upset him less than at any other time.

Acute Excitement.

Severe but manageable excitement is commoner than an outburst of really acute "raving" mania. The condition is marked by emotional exaltation and rapid flow of ideas with greatly increased activity of body and mind. The more acute the excitement the more obvious is the impaired power of attention and the lack of control. In a really acute case the flow of ideas is so unchecked, and the power of attention and control so completely removed that the patient is completely incoherent and incapable of any continuity of thought or fixity of purpose. For this very reason, however, many such cases are, if anything, less troublesome to treat than those not quite so ill, who retain sufficient directive power to attempt to give effect to their unsound judgments and mistaken ideas. Maniacal patients are highly distractible and the ease with which their thoughts, speech, and actions can temporarily be diverted from one channel to another by a tactful and ready-witted companion is an important factor in treatment. Even the mildest cases, however, tend to remain noisy, interfering, argumentative and obstreperous, and are a source of great trouble whether at home or in a mental hospital.

The commonest error in the everyday management of such patients is an undue "humouring" of them by those who have to do with them. To show timidity in the presence of such a patient or to assent to his most outrageous statements with a would-be soothing, but obviously artificial "yes, yes," is apt merely to increase his emotional exaltation and aggravate his condition. Far better results are obtained by a tactful appeal to the patient's boisterous enthusiasm, his sportsmanship, his sense of fair play, and so on. Only in the most acute cases will such measures altogether fail. Many physicians, unfortunately, have at one time or another had to adopt similar measures with persons in certain stages of alcoholic intoxication, and indeed the resemblance, from this point of view, between the two states is very considerable. In many cases the excitement is far more evident in speech than in action, and vice versa, and in dealing with the patient advantage can often be taken of this fact. Many a patient in considerable excitement will remain comparatively quiet in a room, or even in bed, if he is provided with an ample supply of writing materials with which to produce innumerable letters and drawings. Others again will be perfectly quiet if given opportunity to walk vigorously about the garden, while others will sit motionless in bed talking incessantly. A case of any real severity should be kept in bed, if at all possible, though this is often a very difficult task, and it may sometimes, as indicated above, be wiser to allow the patient to be up. The patient's impaired power of attention makes it impossible for him to give due regard to his clothing, his appearance, or even the ordinary calls of nature without constant supervision and control. The physical state of such patients suffers very much less than might be expected. Short irregular intervals of rest and sleep seem to suffice for the time being to prevent a serious degree of exhaustion, and a parallel state of affairs exists as regards food. This is frequently refused altogether or ignored owing to the patient's inability to attend to it for long enough, but the majority of patients take sufficient at one time or another to make tube feeding unnecessary. The way in which a meal is presented to the patient often decides whether it will be hastily gobbled up or flung on the floor.

The best drug for sustained excitement is, without question, sulphonal, properly given. Sulphonal is almost insoluble in cold water, and if given thus or mixed with solid food it is an uncertain, cumulative, and highly dangerous drug. In boiling water, however, it has a solubility of no less than 1 in 15, and though this, of course, rapidly decreases as the temperature falls, it remains quite considerable at body temperature. The drug should be dissolved, therefore, in boiling water, not less than 1 oz. to every 4 or 5 gr. of sulphonal, some vehicle, such as milk or alcohol, added and the mixture drunk hot. Given thus, its administration can be continued for weeks at a time, if the patient's bowels are kept well open, without fear of unpleasant toxic effects. The dose depends upon the patient's condition. At first it may well be 20 or 30 gr. a day, in three doses, but thereafter the patient can generally be kept sufficiently under the effect of the drug by doses totalling 15 gr. in the day or even less. For sudden, uncontrollable outbursts of excitement morphine and hyoscine must be given (gr. $\frac{1}{4}$ with gr. $\frac{1}{75}$). Hyoscine alone, in spite of its marvellous efficacy in certain instances, is too unsafe and uncertain a drug to be recommended for the home treatment of an acute case.

Heroic doses of calomel used to be held in great esteem in the treatment of acute excitement. The writer has little experience of the method, but there is considerable evidence that the drug has a distinctly sedative influence, apart from that produced by the profuse purging which it brings about. Some authorities believe in the administration of croton oil. The continuous warm bath is probably one of the best means of treating acute excitement, but, though quite possible, it is rarely easy or convenient to adopt this measure in a private house.

General Points

If a mental case of any acuteness is to be treated at home, the physician should insist upon at least two trained and qualified mental nurses being engaged, one for day and one for night. Nursing help from members of the patient's family is almost never satisfactory, though it may often be made use of to relieve the nurse for meals and time off duty, a matter for which provision must be made one way or other.

Mental patients are invariably much more difficult to manage, from the nurse's point of view, in their own homes than in a hospital, and, in addition to this, the nurse will not improbably meet with difficulty as the result of the fussiness, suspiciousness, or nervousness of the patient's relatives. The physician owes it to the nurses to give them the very fullest measure of support and to ensure that they have full authority in his absence, and are safeguarded from interference. The instructions he issues to them and the reports he receives from them should be more than usually detailed and explicit.

Two great practical requirements for the physician treating an acute mental case at home are: ability to use sedative drugs wisely, and readiness to resort confidently to tube feeding at the proper time. A working knowledge of the lunacy laws will save the practitioner much trouble, and the ability to talk to, and deal with, mental cases, generally speaking, as if they were ordinary sick people, is perhaps most of all to be coveted.

THE CAPITATION FEE FOR INSURANCE PRACTICE.

Further Session of the Court of Inquiry.

The Court of Inquiry appointed by the Minister of Health to determine the capitation fee payable to insurance practitioners as from Jan. 1st, 1924, resumed its sittings on Jan. 8th in the Ministry of Health. The members of the Court are Mr. R. T. Hughes, K.C., chairman, Mr. F. C. Goodenough, and Sir Gilbert Garnsey.

Tuesday, Jan. 8th.

Mr. E. J. Strohmenger, C.B., Accountant-General to the Ministry, referred to the amended figures for cost of living in 1923 which Prof. Bowley had prepared on the suggestion of the Ministry. The new figures showed a fall in the cost of clothes and food, but they still showed an increase in the cost of fuel and light, although the Department were advised that there had been no change. Personal expenses and the cost of household supplies had also fallen since 1920, but Prof. Bowley's figures did not show this. Even on the doctors' calculations a fair comparison between 1920 and 1923 showed a fall in a comparable standard of living which was certainly no less than the fall in the Civil Service bonus. The Department were of opinion that the Civil Service bonus test was the fairest to apply; it involved no contentious assumptions as to the standard of living. The Ministry had made no pre-war comparison; no one could say what was the pre-war value of the present services required from insurance doctors. The only firm figure was the 11*s.* of 1920.

Prof. Bowley, questioned by Dr. Brackenbury, said that although, at the request of the Ministry, he had prepared alternative figures for 1923 he regarded his original figures as more valid and considered that the altered conditions affecting the doctor's budget for 1923 should be taken into account.

The Experience of Insurance Committees.

Mr. E. R. Abbott presented the case of the National Association of Insurance Committees and the Association of Insurance Committees for Wales. He said that the National Association of Insurance Committees had been formed in 1913. Section 31 of the National Insurance Act, 1913, authorised insurance committees to pay a subscription as part of their general expenses towards the funds of such an Association, and his Association, which represented 118 committees, could therefore claim to speak with an authority which was recognised by Act of Parliament. Of the members of every insurance committee three-fifths represented insured persons who were members of approved societies, the remaining two-fifths represented doctors or chemists or were appointed either by the local authority or by the Minister. The principal duty of the insurance committee was to administer medical benefit under the Insurance Acts; if anyone had authority to speak on the character of the medical service given to insured persons it was they, for they were in continual touch both with the doctors and the insured persons.

The Association had sent a questionnaire to all insurance committees; the Christmas holidays had delayed matters, but in spite of that, replies had been received from 24 county and 48 county borough committees. The replies stated unanimously that the service given by insurance practitioners had been faithfully rendered. In considering the complaints which were sometimes alleged against the medical service, it was often not sufficiently realised that the doctors not infrequently had very difficult persons to deal with. His insurance committee (Middlesex) had, since 1920, been called upon to investigate only 13 cases of irregular certification and 7 of these had been dismissed.

The Rev. William Dennis Yoward, President of the National Association of Insurance Committees, gave evidence in support of the replies given by the individual insurance committees. He explained that the Association had been in session in October when the question of the 1924 capitation was being considered, and the executive council had been authorised to take any action which might become necessary in connexion with that matter. In his experience the insurance doctors had carried out their duties in a proper spirit; his own medical service subcommittee had had only one case of negligence and one case where the doctor had tried to charge fees improperly; there had been similar experience in other districts.

Replying to questions by the Chairman on the specific points raised in the questionnaire, witness agreed with the unanimous expression of opinion that the contracts made by insurance practitioners, taken as a whole, had been faithfully rendered, and that the service was such as might reasonably be expected of average general practitioners. He agreed with the view generally expressed by the committees that there had been an improvement in the quality of the insurance medical service since the inception of the National Insurance Act; as regards diagnosis and treatment there had, in his opinion, been considerable improvement. He also thought there had been a great improvement in the medical service as compared with the facilities available in pre-insurance days. He considered that, with one or two exceptions, insured persons receive as good a service as is rendered to private patients in similar positions. He agreed with the views of the committees that the doctors had not taken unfair advantage of their right to claim that certain services did not fall within the terms of their contract; his experience showed that the doctors had not only fulfilled their contract, but had often gone beyond it without asking for special payment. He agreed with the almost unanimous opinion of the committees that doctors were not reluctant to visit cases needing treatment at home.

In reply to Sir Gilbert Garnsey, Mr. Abbott stated that the total number of insurance doctors for England was just over 12,000, and the number of insured persons 12½ million.

Sir Gilbert Garnsey said that from the complaint figures given by Mr. Brock on the previous day it appeared that on the average one insured person in every 12,000 complained once every four years—this seemed a very small number.

The Chairman: An amazingly small number.

Mr. Edwin Potts, hon. secretary of the Association, said that he fully agreed with the evidence of the Rev. Yoward. In his experience the average insurance doctor did not, before rendering a doubtful service, inquire whether he was obliged by his contract to do the work; he gave the insured person the treatment which his condition required. The returns from 81 committees showed that since 1920 there had been only 456 questions raised with regard to the range of service, although there had, during the same period, been 2369 claims for special fees for anæsthetists' services. In one county, although 706 fees had been paid for anæsthetists' services, no question had been raised as to range of service. The witness thought that the insurance service compared favourably with pre-insurance contract service; it was more settled and stable, and he hoped to see it extended eventually to the dependents of insured persons.

Sir Thomas Neill said that he wished the Court to be informed of the fact that the questionnaire sent to the insurance committees had not, in fact, been considered or approved by the committees in full session. He did not say that the answers would have been different had the committees been able to consider them, but he wished to make it clear that the representatives of the insured persons had not had the opportunity of considering the replies.

Twenty county and 23 county borough committees had not replied to the questionnaire. When the committees met there would be discussion on the matter, and possibly the Court would have representations made to them at a later stage. Dr. Cox inquired whether Sir Thomas Neill proposed to take the opinion of all members of approved societies before submitting his evidence. In reply to the Chairman, Sir Thomas Neill said he did not wish to ask the witnesses any questions, because in his view the proper evidence was not before the Court, having regard to the fact that the replies had been drafted by the chairman and clerk of the committees, and sometimes by the clerk only, but not by the full committee.

The Chairman suggested that as three-fifths of the insurance committees represented members of approved societies, the chairman should often be a society representative. He was very anxious to consider the matter from every point of view. They would take into account the method by which the answers to the questionnaire had to be prepared, but he could not help feeling that the view expressed by 80 out of 123 committees probably represented the general opinion.

The Medical Service in Scotland and Wales.

Mr. F. Llewellyn Jones, giving evidence on behalf of the Association of Welsh Insurance Committees, said that he was satisfied that there had been an improvement in the medical service under the Insurance Acts. Practically all medical practitioners in Wales were insurance practitioners also. Questions as to range of service were almost unknown. He had found that whenever important questions affecting the medical service had arisen, the medical members of the insurance committee had considered the complaints in a judicial manner. In reply to the Chairman, witness said he had no reason to suppose that those committees who had not answered the questionnaire would have disagreed with the replies before the court, or that the replies of the chairman and clerk did not represent the views of the committee as a whole; in the case of his own committee (Flintshire) the vice-chairman, who was the representative of an approved society, had endorsed the answers. Replies had been received from all the large committees.

Mr. W. M. Marshall gave evidence on behalf of the Scottish Association of Insurance Committees. Thirty-five replies had been received to the questionnaire. Both his executive committee and the committees who had replied agreed that the medical service had been and was a good one, in the main. There were bound to be occasional cases of neglect and of irregular certification, having regard to the numbers of insured persons and doctors concerned, but during the last two and a half years the number had been negligible. There had been only 29 cases of complaints as to treatment, and of these ten were not sustained. He agreed that, on the whole, insured persons were treated as well as private patients. In 11 years no case had been raised in his area (in which there were 220 insurance doctors) as to whether any service was or was not a general practitioner service. Throughout Scotland there had been only two cases of disagreement between the local medical committee and the insurance committee on a question of range of service. The usual county insurance practice was 300 to 500 patients; for boroughs it was 1000 to 2000. The number of services per insured person per annum varied widely. In some country areas it was as low as two; in more populous districts it was as high as four; while the figures of a doctor with a panel of 750 patients in a mining village showed nearly five services. In reply to Sir Thomas Neill, the witness said that many people might hesitate to complain against their doctor, particularly in areas where only one doctor was available.

Dr. Gordon Ward, on behalf of the Medical Practitioners' Union, put in further figures on some of the points which had been raised by the Ministry. An analysis of the advertisements for the sale of practices which had appeared in THE LANCET during 1923 showed an average minimum fee in private practice of 3*s.* 6*d.* The National Deposit Friendly Society operated much on the lines of the national insurance scheme, and the average fee there worked out at 4*s.* to 5*s.* a service. As regards the number of services which a doctor could perform in a day, witness instanced the case of Kent, where the maximum number of services would be 25, because the population was not large enough to allow a greater amount of work being distributed among the doctors practising there. Although advertisements had been mentioned which quoted the size of the panel practice, it must be remembered that in very many advertisements the vendor stated, as an inducement to purchase, that there was no panel.

The Ministry's Case.

Mr. M. L. Gwyer, solicitor to the Ministry, then closed the case for the Ministry. He said that he wished to emphasise the fact that the Ministry had not attempted to fix a capitation fee on the basis of ensuring a whole-time living wage; they did not offer a fee which would insure the medical profession against unemployment or insufficient practice, neither were they concerned with the number of potential patients. Their case was that for the time and trouble which a doctor gives to his insurance patients a capitation of 8*s.* 6*d.* was fully sufficient. What the doctor did outside and beyond his insurance work could not enter into their calculations.

Although the Ministry had suggested a total of 24 services a day for half-time work, it was interesting to note the results obtained from the figures submitted by the Insurance Acts Committee. A net income of £1200 represented a gross income of £1400; the half of this—£700—represented a list of 1650 insured persons at a capitation fee of 8*s.* 6*d.*, and on a 3·5 attendance basis this would mean 19 services daily. If, as was suggested, the present capitation fee was insufficient and failed to attract men to the service, why was it that the number of panel doctors had increased even since the fee had been reduced from 11*s.* to 9*s.* 6*d.*? It might be thought that the Ministry had been too meticulous in their calculations, but the service covered so great a number of insured persons that fractional calculations were of importance; a variation of every shilling in the capitation fee represented £750,000. In conclusion Mr. Gwyer expressed the hope that the Court would indicate in their report for what period the new capitation fee should be applied.

The Chairman inquired whether the Court was able to fix a period binding on both parties, or whether in this respect they could merely make a recommendation.

Mr. Gwyer replied that the parties had agreed to accept the capitation fee for a period of one year; any recommendation for a longer period would, of course, be treated with great respect, but would not be binding.

Dr. Brackenbury agreed, but said that the profession definitely did not approve the principle that an award for a longer period should be at a lower figure.

Dr. Ward expressed the hope that an award for a longer period would not be regarded by the Minister as taking the place of the Royal Commission which had been promised.

Private Contract Rates.

Dr. Cox made a statement on the figures quoted by Mr. Jeffrey for Scottish contract practices. Mr. Jeffrey had tried to show that the fee of 9*s.* 7*d.* for Scottish colliery districts was really only worth 7*s.* 1*d.*, yet in 1919 when the Scottish doctors were negotiating with the miners they had agreed to accept as the general basis the count in a certain mining village, and that count had resulted in the average figure of 5·25 dependents, which gave an equivalent of 9*s.* 7*d.* Mr. Jeffrey had quoted some of the lower capitation rates which existed in contract practice,

yet there were many high rates also. Thus, in Leicestershire 41,000 persons received benefit under a scheme which paid 13*s.* per head for treatment and medicine; the same figure applied to Bournemouth and Southampton. It would be unfortunate and entirely wrong if the doctors were put at a disadvantage as regards insurance practice because they were in certain instances accepting a low rate for dependents. The cases were not parallel. Treatment for dependents did not involve the keeping of the official records or the issue of onerous certificates, and many services carried a special fee. If the doctors, following the tradition of the profession, gave treatment to dependents at a rate lower than the average it would be unfair to penalise them on this account in respect of their other work. He had frequently warned the profession that an attempt would be made to reduce their capitation fee by a reference to some of the rates for contract treatment to dependents.

The Doctors' Case.

Dr. Brackenbury then concluded the case presented on behalf of the doctors. He said that he did not propose to deal in great detail with the comments made by the other side, because in his view there were certain broad principles which would necessarily determine the question. As to the range of service, he was content to accept the statement made on behalf of the Ministry and the evidence of the insurance committees. Every insured person was, however, entitled to the services of a second doctor in an emergency, the payment for that service coming out of the pool provided by the capitation fees. An insured person could also claim the services of a second doctor whenever his own doctor was away, and there was a similar provision when an anæsthetic was required. These facts were material in any comparison made with private practice.

It was said that in spite of a reduction in the capitation fee there had been a sufficient entry into the service. This might be true as regards total numbers, but the average doctor could not avoid undertaking insurance practice, and it was therefore illogical to say that the terms were adequate because the doctors undertook this class of work. At present many doctors starting in practice asked themselves "How can I avoid insurance work?" The Insurance Act would not have attained its object until there was a willing service by the doctors. There might be a sufficiency in the total number of doctors without an adequate distribution. There were industrial areas offering little or no practice outside insurance work. To attract doctors to those areas you must make it worth their while either by a differential capitation fee or by taking those circumstances into account in fixing the uniform capitation fee.

They had been criticised for their comparison of the responsibility of insurance practitioners as between 1913 and 1923, but they considered that if the Court desired to make a comparison between those years the cumulative effect of the additional services required from the doctors should be taken into account. Even in 1913 both the State and the doctors intended insured persons to have a full general practitioner service, but the conception of what that involved had developed in the intervening years.

The Ministry contended that the convergence of the results shown by the Ministry's different methods of calculation proved the correctness of the results; but there was equal convergence of the results obtained on their side. The doctor's case was that the fee of 7*s.* 3*d.* of 1913 or 11*s.* of 1920 should be applied to present-day conditions. It was suggested that both these figures should be abandoned as a basis of calculation, but he did not agree. The arbitrators in 1920 gave no explanation of the method by which they had arrived at their award, and he was at least entitled to assume that (as certain calculations which he had made seemed to suggest) they did accept the 7*s.* 3*d.* basis. It had been said that the 11*s.* rate would have been less had it not been for inflation; but he was equally entitled to say that had the arbitrators known that prices would continue to soar—as they had done—after the date of the award, they would have fixed a higher figure. As to the cost of living figures on which the doctors' case was based, Prof. Bowley's tables for 1920 were generally admitted to be valuable. Prof. Bowley had taken the actual figures for 1913 and had then applied them to 1920 by considering the actual middle-class budget for the latter year; now, in 1923, he applied the same principle by asking what was a reasonable way in which a similar budget would be expended at the present time. It was unfair to write up the 1920 budget for purposes of comparison with 1923 unless the 11*s.* capitation fee of 1920 were also scaled up and adjusted. Even if they considered the amended figures, the new capitation fee would be 10*s.* 4*d.* or 9*s.* 2*d.*, according to whether it was worked out on the 7*s.* 3*d.* or 11*s.* basis.

As to practice expenses, it was true that in some of the paragraphs of their printed case they had taken 16 per cent., but this did not represent their view of a reasonable figure. In previous years they had worked on the 25 per cent. basis and the Ministry had accepted that percentage; his colleagues were very emphatic that even this was too low, certainly as regards small practices and large practices. Mention had been made of cases where the minimum fee of 1*s.* 6*d.* was charged in private practice, but he suggested that such instances should be ruled out; the Insurance Act had been introduced to put an end to that sort of thing. A minimum fee mentioned in an advertisement represented the absolute minimum charged to any of the doctor's patients; it was not necessarily the normal or average figure and might be applicable only to a few patients.

Regarding the time equivalent, they did not quarrel with the instructions which had been issued to regional medical officers in connexion with the examination of the records on which the Ministry's figure of 3·5 services per insured person per year had been based; but they did say that it was almost impossible to carry out those instructions in detail. His committee had collected statistics affecting over 600,000 insured persons, and these showed the correct figure to be 3·77. During the 1920 arbitration the Ministry had themselves adopted the figure of 3·8. It was significant that in Manchester and Salford, where it was to the direct interest of the doctor to keep a careful record of all visits and attendances, the figure was 4·35. He suggested that it was not, in any case, safe to work on the lowest figure which had ever been arrived at and which had been determined with reference to a particular year. The profession were making no extravagant claim in suggesting that the calculations should be made on the basis of 3·8.

As to the number of services which would occupy a doctor's whole time, the calculation of 300 working days of eight hours each, allowing only Sundays free and a fortnight's holiday in the year, was in itself fairly severe. Further, it was wrong to take account only of the time occupied in actually seeing the patients. To that must be added the time for writing the certificates, records, &c. required by the Regulations, and there was also the professional thought, consideration, and reading which the doctor had to give to his work: it might be difficult to translate this into a time equivalent, but it was a very real factor to be taken into account. It had been suggested that 10 consultations might be given in an hour, but in his opinion that could not be done; it might be possible for routine work, but in the midst of the routine work there would arise a special test or other special service which would hold up the doctor for a considerable time; even 5 per cent. of special cases occupying 10 per cent. of extra time—a low estimate—was a factor to be considered. The Ministry's case was based on a high number of working days per year (300), a high number of services per day (48), and a low service rate per insured person per year (3·5). In his opinion that represented an amount of work which could not be done with justice either to the doctor or to the patients. Dr. Smith Whitaker had suggested that if 2000 insured patients would take up more than a doctor's half time, let them assume a fraction of four-sevenths; if they did that the

capitation fee of 8*s.* 6*d.* would at once be raised to 9*s.* 9*d.* The Ministry had said that the 8*s.* 6*d.* capitation fee was equivalent to a service fee of 2*s.* 5*d.*, which, in turn, was worth the equivalent of 3*s.* in private practice. Even accepting the latter figure the fee would be very moderate, but he suggested that if one made an addition to the 2*s.* 5*d.* figure because there was no cost for medicines or collection, and no bad debts, a corresponding reduction should be made for the additional work which had no counterpart in private practice—e.g., certificates, the provision of a second doctor, &c. In conclusion, Dr. Brackenbury expressed the opinion that the profession had been modest rather than extravagant in assessing the value of their services to the State and to their patients.

At the close of Dr. Brackenbury's remarks, the Chairman, amidst general applause, said that the profession were fortunate in having so able an advocate.

The Court adjourned until the 15th to hear the evidence of certain independent approved societies. The main case of the approved societies will be stated on the 21st.

FOOD IN RELATION TO HEALTH AND DISEASE.

FOOD in its relation to health and disease can be considered broadly in two aspects: firstly as a medium by which disease may be spread throughout the population, and secondly, as an economic and dietetic problem, whereby the standard of nutritional value is maintained. It is the duty of the Ministry of Health to supervise the food-supply of the country with these two objects in view—the control of disease and the prevention of adulteration. How this duty has been construed is made clear in the passages from the report of the Chief Medical Officer which are here summarised.[1]

Milk: Production and Distribution.

The importance of milk as an article of diet has long been recognised by those concerned in the investigation of nutritional requirements, but of all foodstuffs milk and its products have been the most blamed for the spread of disease on the one hand and have been most often adulterated on the other. Hence the necessity for the very strict control of all that appertains to the dairy. Since 1885 the sanitary authorities have administered regulations for the maintenance of a clean milk-supply, but even now at least 5 per cent. of the milk coming into London, when sampled at the termini, contains tubercle bacilli. As the importance of milk as a possible source of infection, particularly of tuberculosis, became more and more evident, a scheme of grading the milk according to its purity was introduced in the Milk and Dairies (Amendment) Act of 1922, and the Milk (Special Designations) Order of 1923 sets forth the principal conditions applying to the various classes of milk.[2]

The system of licensing involves the inspection by the Ministry of farms and retail depôts in various parts of the country. Such inspections include a survey of the methods of milk production by means of the score card, the identification of animals in the herds, the methods of handling, bottling, and distribution, and compliance with the regulations for the several grades. The growing interest taken by milk producers, distributors, and consumers in the supply of a milk of special purity is indicated by the steady increase in the number of licences for which application is made, but at present the amount of this high-grade milk supplied is almost negligible. The production of such milk has a substantial educational advantage and proves the practicability of an improved milk-supply for all consumers.

It is important that the general public should realise the advantages of milk as a food, especially for growing children. Hitherto this country has been very backward in this respect, the average consumption per head of milk in Great Britain being less than one-third of that amongst the people of the United States. In fostering such a movement those concerned will do well to give due consideration to the many factors which account for the relatively small consumption of milk in this country. Amongst these not the least important is the unsatisfactory condition as regards cleanliness of a considerable proportion of our milk-supplies. The importance of obtaining a good name for milk in this respect should not be overlooked. The conversion of our population to a satisfactory standard of milk consumption will depend very largely on the energy displayed by all concerned in raising the whole standard of milk production and distribution to a level such as that which has already been reached by milk produced under the grading scheme. What does this involve? First, clean and healthy milch heads; secondly, clean milking; third, effective cooling of the milk immediately it is obtained; lastly, prompt bottling at the farm, or clean and rapid transit in bulk. These appear to be simple requirements, but their fulfilment demands thorough and continuous attention to detail and good organisation. For consumption in industrial towns there is much to be said for the use of pasteurised milk, but pasteurisation cannot make dirty milk clean; to be wholesome and to have keeping properties the milk must itself be clean.

Notwithstanding the numerous difficulties which present themselves in bringing offences home to milk adulterators, local authorities, as a whole, show commendable zeal in endeavouring to maintain its purity in this respect. The returns furnished by public analysts show that in general milk as sold to the consumer is satisfactory as regards milk-fat and other milk solids.

Food Poisoning.

During the past year a considerable number of outbreaks of food poisoning were reported. The origin of these outbreaks was investigated by local officers or by means of inquiries made by medical officers of the Ministry. It would be of assistance if the coroners understood that the bacteriological examinations should be made at the Bristol University by Mr. Bruce White, the material being forwarded by the doctor making the post-mortem; at times in large towns this doctor has practically an appointment and may think he loses dignity if the bacteriological work is not carried out by himself. The causes of food poisoning may be classified as being due to chemical poisoning, to bacterial invasion, or to ingestion of toxins contained in food. Lead, copper, and zinc from vessels employed in the distribution of beer and soda-water were responsible for some cases of chemical poisoning in London and Manchester. A case of zinc poisoning which occurred at Ipswich caused the local authority to issue a warning to the public against the making of jam in galvanised iron vessels. In this case a sample of home-made jam was brought to the local health department as it had been found to have a peculiar flavour. It had been made in a galvanised iron pan. The public analyst found that the jam was contaminated with zinc to a poisonous extent.

A large amount of work has been done in perfecting the electrolytic method of estimating arsenic. An apparatus has been evolved which constitutes a great improvement on previous types, and is likely to be adopted in other laboratories in preference to the zinc and acid method. During the year arsenic was discovered in samples of cocoa, tea, baking powder, and food wrapping papers, but no poisoning resulted in consequence. Arsenic had gained access to the cocoa, though not in deleterious doses, by means of potassium carbonate, contaminated with this substance which had been used in the preparation of cocoa to increase its solubility.

[1] Annual Report of the Chief Medical Officer of Health for the year 1922. H.M. Stat. Office, 1923.
[2] THE LANCET, 1922, ii., 1397.

Bacterial poisoning occurred on a considerable number of occasions in the last 12 months. In some, one person only or one family was attacked and the matter came to notice on account of the holding of an inquest. Other outbreaks, however, were on an extensive scale. The articles of food which came under suspicion as the cause of illness were of the most diverse nature. In many instances an organism of the Salmonella group was isolated. Outbreaks due to cheese are of interest, as in four instances cheese of Canadian origin gave rise to poisoning, on two occasions on a considerable scale; analysis of the cheese failed to reveal food poisoning organisms, but a water-soluble toxin was found to be present. Agglutination tests for the presence of members of the Salmonella group gave negative results, but in a small outbreak of food poisoning due to Wensleydale cheese positive results in this respect were obtained. Tyrotoxicon was not found in any of the cheeses.

Exaggerated Dangers.

The ingestion of toxins contained in food was exemplified by the outbreak of botulism at Loch Maree in August, 1922. The dramatic circumstances of the case directed public attention to possible dangers of poisoning which, though alarming in themselves, are less so when viewed in their relative proportions. A wholesale condemnation of preserved meats through fear of botulism or any other disease is both rationally and economically unsound. Of necessity, canned and prepared foods now enter largely into the dietary of the British public, and form an important and valuable part of the food-supply of the nation. That illness of one sort or another should occasionally result from their use, as it does from other forms of food, is well-nigh inevitable. Having regard, however, to the enormous quantities of canned and prepared foods consumed, the remarkable fact is, not that accidents should occasionally occur from their use, but that these accidents should have been so few and far between. In this connexion, it should be remembered that the outbreak at Loch Maree is the only authenticated instance of the occurrence of botulism in this country. The illness was attributed to the consumption of wild duck paste, prepared and put up in small jars in one of the best equipped and managed factories in London. A very large number of jars were all prepared at the same time and in exactly the same manner, yet only one jar out of a total of many thousands gave rise to botulism, the contents of the others apparently having been consumed without ill-effect of any kind. Alarm in respect of water-supply, milk, and food, may sometimes be justifiable and salutary, but unless the circumstances are quite exceptional such alarm may prove to be extremely damaging both to the national health and to national industry. Flour, cheese, milk, tea, coffee, cocoa, meat, and prepared foods form staple and universal articles of dietary, and sporadic or accidental contamination here and there should not so disturb the public mind as to lead to widespread condemnation or discarding of these foods. An accident, tragic and regrettable in itself, affecting a single household or a dozen persons may in these days of ready intercommunication be so widely announced and amplified as to lead to the deprivation of millions of people of their usual food and to irreparable damage to great industries, resulting in extensive unemployment and serious financial loss.

The immediate result of this outbreak was an investigation of the methods employed by a certain great food manufacturing firm in securing sterilisation of their products. These were found to be eminently satisfactory, and are all embodied in the steps which Sir George Newman details in his report for the protection of the consumer. The measures adopted are stringent and the habitual practice of them involves a thorough, sound, and comprehensive health administration of a factory. But experience shows that such an administration is practicable and business-like. If the custom and confidence of the consumer are to be secured and retained, such an administration, a sort of "industrial health conscience," is necessary. To be efficacious, and free from hazard and chance, such a health administration must be a partnership between four parties—(1) the manufacturer, (2) the central health authority, (3) the local sanitary authority, and (4) the public, as consumer. The consumer has his own responsibility in the domestic preparation or purchase of food. He is represented by public opinion and by the press. Both are of the utmost value in affording information, providing education, and raising the standard of the food-supply, and, as a corollary, the health and efficiency of the nation.

WORK OF THE FOOD INVESTIGATION BOARD.

In this department of the Committee of Scientific and Industrial Research the outstanding event[1] of the year is the equipment of the Low Temperature Research Station at Cambridge up to the point at which work could be begun. The research staff took charge and began work in June, 1922; the equipment of the station is not yet complete, but the first floor, devoted to fruit and vegetable work, was ready for the apple harvest, and the freezing tanks were ready in October, when the first lot of fish were frozen in them. Four chambers at the station have already been fitted with automatically controlled electrical heating; the designing and testing of this equipment has taken much time, but it has been found possible to maintain temperatures in these rooms over long periods with no greater fluctuation than 0·05 of a degree—an accuracy hitherto only obtained on a small scale by the employment of incubators. The facilities now provided will enable experiments involving bulky apparatus to be carried out.

The station was intended to fulfil two allied purposes—first, to act as an instrument for research carried out by the various committees of the Board, and incidentally to offer to workers in other laboratories of the University its own peculiar facilities for research in which low temperatures are required. Thirty-five such research workers at one time or another made use of it.

During the year under review a new development of the Board's activities took place, along lines laid down in 1918, of an intensive study of the physiology of the ripening process of a single fruit under normal and storage conditions. The apple was selected for this purpose, and when this investigation is completed other fruit will be studied in a similar fashion. The Board was asked to organise a small expedition to investigate, during an entire voyage from Australia, the gases in ships' holds in which apples were carried, and especially to compare the different methods in use for cooling the holds. The expedition left early in the year.

A brief abstract is given of the work of the Fish Preservation, Meat Preservation, Engineering, Fruit and Vegetables, Oils and Fats, and Canned Food Committees. The general theory of the freezing of tissues promises to be substantially advanced by the discovery made in connexion with experiments upon eggs that preservation does not depend upon a critical rate of cooling being exceeded, but upon the rate of cooling falling within certain limits. When these are observed, the changes which take place on freezing are reversed in thawing; when they are exceeded, the changes are irreversible.

[1] From the report of the Committee of the Privy Council for Scientific and Industrial Research for the year 1922–23.

SMALL-POX IN ENGLAND AND WALES.—The number of cases of small-pox notified in England and Wales during the week ended Jan. 5th had risen to 115, distributed as follows: Derbyshire 39 (Bolsover 2, Chesterfield 20, Heanor 4, Swadlincote 7, Blackwell R.D. 4, Chesterfield R.D. 1, Shardlow R.D. 1); Gloucestershire 26 (Gloucester 3, East Dean R.D. 23); Leicestershire 14 (Ashby Woulds); Northumberland 2 (Bedlingtonshire); Notts 34 (Hucknall 21, Kirkby-in-Ashfield 12, Basford R.D. 1).

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

Provision for the Treatment of Ophthalmia Neonatorum.

THE Scottish Board of Health has issued a circular to the local authorities emphasising the fact that ophthalmia neonatorum is a preventable disease, and that even where it occurs its disabling effects can be avoided by prompt and adequate measures of treatment. Advance has recently been made on these lines, but cases still occur in spite of the efforts of medical practitioners, midwives, and public health authorities. As a source of blindness, ophthalmia neonatorum is of first importance, and blindness, apart from the disaster to the individual, involves a very serious charge upon the community in the maintenance and education of totally or partially blind persons. The Board are impressed with the necessity that every local authority administering a scheme of maternity service and child welfare should make adequate provision for the hospital treatment of this disease, for in their opinion few, if any, cases can be treated at home with any degree of safety. Ordinary nursing is not sufficient; treatment must be carried out by a specially trained staff, therefore the Board requests all local authorities to make definite arrangements with a suitable hospital where such skilled treatment may be obtained, for accommodation cannot be satisfactorily improvised on the occurrence of a case. It is also desirable that accommodation be provided for the mother to accompany the child wherever it can be arranged. This provision is all the more necessary, as the possibility of secondary infections is recognised as an important factor in the continued incidence of the disease, and special precautionary measures are required where there is any reason to suspect a risk of infection from the mother. While it is essential that no delay should arise in providing treatment for any case, the Board realises that the cost and inconvenience of maintaining suitable accommodation in the smaller infectious diseases hospitals would be burdensome, as in most areas the annual case incidence is not large. To avoid this difficulty local authorities outside the larger centres of population are advised to make arrangements with some institution already providing the necessary skilled attendance. The net cost of such treatment is a competent charge on the child welfare grant.

With regard to cases in which the necessity for removal to hospital is not immediately apparent, it is the duty of the local authority to provide adequate skilled nursing at home, the cost of this provision being also a competent charge on the child welfare grant. In such cases the medical officer of health should, through the health visitors or visiting nurses, ascertain progress from day to day, in order that hospital treatment may be at once commenced if the disease shows any tendency to become more serious. As the total number of cases for Scotland is small, the expense of making suitable arrangements will not be heavy; indeed, compared with the cost of education and maintenance of persons blinded by neglected disease it will be negligible.

Measles in Glasgow.

A meeting of representatives of local authorities and medical officers of health from the larger areas in Scotland specially interested in the prevention and control of measles during epidemic periods was held on Jan. 10th in the offices of the Scottish Board of Health, Edinburgh. The meeting was convened by the Board with special reference to the recent epidemic of measles in Glasgow and contiguous areas and to the continued high proportion of deaths from the disease that occurs in children under school age. Captain W. E. Elliot, Parliamentary Under Secretary for Health for Scotland, presided. The present position and further measures possible for improved control and treatment of the disease, both in rural and urban areas, were discussed in their medical and financial aspects. Captain Elliot intimated a special limited grant from the Treasury to be administered by the Board in conjunction with the present grant in aid of maternity service and child welfare schemes in Scotland. There was a full expression of opinion as to the general lines on which the grant might best be utilised, and the Board will issue shortly a circular letter to local authorities on the subject.

Appointment of Medical Officer of Health for Aberdeen.

On Jan. 7th Dr. John Parlane Kinloch was unanimously appointed medical officer of health for Aberdeen in succession to Prof. Matthew Hay, who recently resigned the post. Dr. Kinloch was educated at Glasgow High School and University, where he graduated M.B., Ch.B. in 1909. Four years later he obtained the degree of Doctor of Medicine with commendation, and the Diploma of Public Health of Cambridge with distinction. While working in the medical health department of Glasgow before the war from 1909–10 in Ruchill Hospital, Dr. Kinloch had every opportunity of studying the problems of public health in its many varied branches. In addition he acted as instructor in public health to students and nurses in Ruchill Hospital. In 1914 Dr. Kinloch was appointed to a lectureship in public health at Aberdeen University and in the following year deputy medical officer of health for Aberdeen. During the war he was attached for a time to the 22nd Mobile Field Laboratory in France. Dr. Kinloch is the author of many publications on public health subjects, and his services ought to prove a distinct acquisition to the public health department and city of Aberdeen.

University of Glasgow.

At a meeting of the University Court on Jan. 10th Principal Sir Donald MacAlister received the congratulations of that body and of the Corporation of Glasgow on his baronetcy. Arrangements were made to coöperate with the Royal Society on the occasion of the Kelvin anniversary on June 25th, 1924.

A further appeal for the preservation of the Lister Ward has been received by the managers of the Glasgow Royal Infirmary. It comes from Ottawa, and bears the signatures of officials of the Canadian Ministry of Health.

HOLLAND.

(FROM OUR OWN CORRESPONDENT.)

Outlook for the Medical Student.

DURING the past year in Holland there occurred an "epidemic" of good health, which coincided with slack times in the business world, and while any improvement in the national health is an encouragement to those who make it their care, nevertheless the combination of these two factors had hardly a favourable effect on the economic position of the medical profession. The amount of work done by doctors amounted on an average to no more than 60–70 per cent. of a normal year, and the income of the non-panel practitioners decreased in proportion. This is not so very bad for old and established practices, but for the young doctors, of whom the supply at present exceeds the demand, these conditions make life rather hard. The more so as the demand for doctors from the Dutch colonies has ceased and as the Government seems inclined to reduce the already small number of Government posts, which in themselves are none too lucrative. Among others, Prof. van der Hoeve, in the *Geneeskundige Gids*, is asking whether it would not be advisable to restrict in some measure the coming generation of medical students. Indeed, something can be said in favour of such limitation, provided a careful selection is made, not from those merely who can afford high training fees, the economically strong, but from those whose moral character, social attainments, and scientific proclivities mark them among their fellows. Such a selection, however, is exceedingly difficult.

It is almost impossible to form a right and just opinion regarding the moral and social qualities of the young medical students, and further, in general practice, the "scientific man" is, as a rule, not a great success. This limiting system is contrary to the Dutch national character; the only thing will be to inform the coming generation now at school about the practical problems and the economic conditions awaiting them. The public at large must disabuse itself of the old idea that doctors are rich men or earn a living easily. Only thus can the true interests of the medical profession be advanced.

Organisation of the Anti-Tuberculosis Campaign.

Up till the last few years the Dutch Government did not concern itself greatly with the fight against tuberculosis. The campaign lay entirely in private hands and was financed to a considerable extent by private contributions and charity. There were no "consultatie-bureaux" (dispensaries). The organisation was fairly primitive and was conducted in a more or less haphazard way. Small local unions paid their visiting nurses, who at the same time acted as district nurses and distributed various treatment appliances as, for example, Dettweiler sputum-flasks. There were no tuberculosis hospitals, and in most cases sanatorium treatment was too expensive for the man of moderate means, nor did the local unions have the funds to provide such treatment on a large scale. Well-to-do tuberculous patients went to Switzerland. Under these conditions the comparatively small number of sanatorium beds were taken up by serious cases in whom hope of recovery was small, a fact which did not increase the popularity of these institutions. The local unions were grouped into provincial unions and the latter formed one central organisation. In the last few years, however, a combination of circumstances has produced a rapid evolution. The reorganisation of the Government inspectors of public health, which resulted in a special investigation into the tuberculosis question, did much to help in this advance. Of still greater importance was the passing of the Disablement Act, which, in virtue of a certain clause, opens the possibility of preventive and prophylactic treatment through the insurance institutions; under this clause a large number of tuberculous patients applied for treatment. Moreover, the investigation committee succeeded in persuading the Government of the necessity of earmarking certain available sums for the treatment of indigent patients, and impressed the authorities with the necessity of efficient organisation in the anti-tuberculosis campaign.

The Dispensary System.

The plan advocated by the committee, and which will now be put into effect, embodies a separate and autonomic organisation of the campaign with the aid of dispensaries. In every district, in every province, and in some of the biggest towns, a district dispensary will be established under the supervision of a medical man, who need not necessarily be a lung specialist, but who must have business ability, as on this score previous undertakings had completely failed. Under him is a district visiting nurse who trains and controls the local visiting nurses. The medical man keeps in touch with the inspection and the provincial union, whereas, practically speaking, the central organisation has been eliminated. The district dispensaries are the nucleus of social and hygienic propaganda and at the same time form a confirmatory court for the family doctors in the diagnosis of tuberculosis. The bureau does not carry out treatment. This scheme is proving a success, also the insurance institutions are sending tuberculous patients to the dispensaries for examination before admission to the sanatoriums. Thus these dispensaries act as "transition" houses for the sanatorium patients, and further they concern themselves with the "after care" of discharged patients. The type of case now accepted by the sanatoriums for treatment is preferably that in which the patient has a good prognosis and a fairly mild infection, such as are likely to benefit greatly by a course of six months' care and hygienic education.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

The Battle of the Clubs.

THE ordinances concerning changes in medical attendance on club members have caused great indignation among the medical profession, as I stated in my letter of Dec. 15th, 1923. Interviews with the Government resulted in the withdrawal of certain clauses, especially those dealing with the erasure of a medical man from the panel during his time of contract if it was alleged that he had acted to the detriment of the club. The concessions of the Government were, however, held insufficient by the profession because the provisions limiting the further admittance of medical men to the panel were not amended. The strike for which preparations had been made ever since the new ordinances were published (and which probably might have been avoided if the concessions had been made earlier and on a more liberal scale), was therefore declared on Dec. 1st by the German Medical Union, the so-called Leipziger Verband. The strike became effective nearly everywhere throughout Germany except in the occupied territory, owing to political and social reasons, and in certain districts of Southern Germany, where the clubs had made common cause with the medical profession. The Leipziger Verband gave notice to the clubs that the contracts had been dissolved under German law owing to a vital change in an essential clause, and the clubs did not challenge the notice. The strike, which is still going on, is not a strike in the strict sense of the word, medical attendance being given individually when required, the club members being treated as private patients—i.e., they have to pay the fee for the consultation or the visit direct to the medical man: the prescriptions for medicine are written not as hitherto on vouchers of the club but on a private prescription form; consequently, the patients have to pay the chemist for their medicine. They can, however, recover the money paid to the chemist and the doctor in every individual case at the club offices, a lengthy and troublesome proceeding. During the struggle both doctors and clubs addressed the members through the press by pamphlets and even by posters, each party accusing the other of provoking the strike for futile reasons. The clubs expressed the opinion that the doctors, to put an end to the clubs, were deliberately endeavouring to destroy the shaky financial situation of the clubs, so that they would cease to exist; the medical men complained that the clubs were willing to make use of the ordinances to get rid of the free-choice system, which had lately been introduced almost everywhere after a long struggle. Mass meetings of club members have also been called in Berlin by the Medical Union, where medical men made use of their ability as debaters inviting the members to assist the medical profession in its struggle against the committees of the clubs. The doctors pointed out that the free-choice system the only system assuring careful attendance to club members, could probably be abolished under the ordinances. Under the system of appointed medical officers members were attended in a cursory manner and did not receive adequate treatment, notwithstanding the heavy contributions exacted. It is noteworthy that at the meetings held in Berlin a vote was unanimously passed supporting the demands of the medical men. Up to the present the "strike" (to use this word which is officially rejected by the medical profession) has been successful, only a few medical men having approached the clubs; their names were, of course, published in the medical press and every professional relation broken between them and their professional brethren. The Arbeits-Ministerium (Ministry of Labour) has tried to arbitrate between the parties, but without success, the only result being that the mutual accusations in the press and in pamphlets were stopped.

Plethora of Medical Journals.

Prof. Unger, one of the surgeons of the Virchow Hospital, draws attention to the fact that in spite of reduced incomes in the profession, which do not allow many of its members to subscribe to medical journals, the number of medical periodicals, though decreasing, is still much too large. Speaking of his own specialty, he mentions that two surgical "Centralblätter" are published in Germany in which every article and every work on surgery is reviewed twice by different writers. Concerning medicine in general, no less than four great medical journals are issued, the *Klinische Wochenschrift*, the *Deutsche Medizinische Wochenschrift*, the *Medizinische Klinik* in Berlin, and the *Münchener Medizinische Wochenschrift* in Munich, and in addition to those national journals there exist many local medical periodicals. He suggests that the publishers should reduce the number by amalgamation. If the publishers will not agree to this, he proposes that the surgeons should henceforth combine in subscribing to only one particular Centralblatt in order to compel the other to amalgamate or to disappear. He also urges the medical profession to act in the same way with the weekly medical papers. According to Prof. Unger, it would be no great loss if some of the articles now appearing in the medical press had never been printed at all, while in the remainder efficient cutting down would save much space.

Underfeeding Amongst School Children.

The Berlin Municipal School Board has lately made an inquiry in 12 of the municipal schools as to the present condition of the children. The results of the inquiry showed a rather sad state of matters: 16·5 per cent. of the children had come to school without having had coffee or warm soup in the morning, 38 per cent. had had no bread for breakfast, 6·38 per cent. had brought no lunch sandwiches to school, 5·06 per cent. had had no warm meal the day before, and 31·2 per cent. had only one warm meal in the day. In 15 per cent. footgear was very defective, and in 16·34 per cent. the clothes were inadequate.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. R. R. Horley is placed on the retd. list with rank of Surg. Capt.

ROYAL ARMY MEDICAL CORPS.

Col. S. F. St. D. Green, late R.A.M.C., to be Maj.-Gen., to complete estabt.

Col. A. J. Poole, on ceasing to be empld., is placed on half pay.

The undermentioned Cols., late R.A.M.C., retire on retd. pay: P. Evans, G. St. C. Thom, E. T. F. Birrell, and E. W. Bliss.

Col. C. W. Profeit, late R.A.M.C., is placed on half pay.

The undermentioned Lt.-Cols., from R.A.M.C., to be Cols.: J. W. H. Heughton, G. M. Goldsmith, R. H. Lloyd, Bt. Col. J. M. Sloan, H. D. Packer, and J. W. Leake.

Majs. to be Lt.-Cols.: Bt. Lt.-Col. A. W. Sampey, H. Rogers, S. M. Adye-Curran, L. Cotterill, W. J. S. Harvey, and Bt. Lt.-Col. B. A. Craig.

Temp. Capt. E. A. Tozer relinquishes his commn. and retains the rank of Capt.

Capt. F. J. Hallinan to be Actg. Maj. whilst empld. as Dept. Asst. Dir. of Pathology.

RESERVE OF OFFICERS.

Maj. and Bt. Lt.-Col. C. G. Spencer, having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

ROYAL AIR FORCE.

Flying Officer F. K. Wilson ceases to be seconded to the Bristol Infirmary.

INDIAN MEDICAL SERVICE.

Lt.-Col. J. A. Black to be Col.

Puranganal Abraham Mathew to be temp. Lt.

Obituary.

GEORGE ALEXANDER HEATON BARTON, M.D. BRUX.

IT is with deep regret that we announce the death of Dr. G. A. H. Barton, anæsthetist to the Royal National Orthopædic Hospital and to the Hampstead General Hospital, who met with a fatal accident when on horseback in Hyde Park on Sunday, Jan. 13th. Dr. Barton, who was 56 years of age, was an old student of St. Mary's Hospital, where he qualified L.S.A. in 1886 and M.R.C.S. Eng. two years later. In 1901 he graduated M.D. of Brussels University. From the first he specialised in anæsthetics, on which he became a recognised authority, his writings including "A Guide to the Administration of Ethyl Chloride" and "Backwaters of Lethe," which first appeared in 1920. Various articles in medical journals dealt with methods and technique of administration.

A colleague writes: "Dr. Barton was not a man of one side only, but it is only on that aspect of him which appeared in his activities as an anæsthetist that I am qualified to speak. Even so, one was able as a colleague to recognise that Barton was no ordinary man. In his work he showed ingenuity, observation, and perseverance. Further, he made it obvious that he possessed a considerable sense of humour, that he had understanding of human nature, and that he was by no means insensible to the literary and artistic sides of life. These qualities appeared also in his contributions to the literature of his own subject. It is of the first importance for an anæsthetist, more so perhaps than any other medical man, to have the faculty of rapid insight into the mentality of the individual with whom he is dealing as a patient, of accommodating himself to that individual's character, and entering into sympathetic control of him. Barton was well qualified to meet the subjects of his administration in this manner, and his success with them depended as largely on this power as it did on the actual skill of his work. The rather elaborate sequence of anæsthetics which he affected was employed by him with much tact and skill and gave in his hands excellent results. Barton had a sly humour which was not easily apparent to those who were not intimate with him, but which will be sorely missed by his friends. He was a man who formed his own opinion on professional questions and did not merely re-echo those of other men. As a speaker, at the old Society of Anæsthetists and later at the Section of Anæsthetics of the Royal Society of Medicine, which bodies he frequently attended, he was always logical as well as tireless. His sudden death is a great loss to his former colleagues as well as to the many patients who appreciated the value of his professional services and of his personal character."

HENRY ARTHUR LATIMER, M.D. DURH.

Dr. H. A. Latimer, a well-known local figure in medical and civic public life, died on Jan. 10th at his residence in Tunbridge Wells, aged 74. Dr. Latimer was the son of the late Mr. Isaac Latimer, J.P., former Mayor of Plymouth. He received his medical education at Guy's Hospital, obtaining the qualifications of L.S.A. and M.R.C.S. Eng. in 1871, later graduating as M.D. at the University of Durham. For 41 years he conducted a successful practice in Swansea, and played an important part in public medical affairs. He was for 13 years a Direct Representative on the General Medical Council, retiring along with Dr. H. W. L. Browne at the end of 1919, and he often presided at the meetings of the South Wales and Monmouth Branch of the British Medical Association. He held appointments as consulting surgeon to the Swansea Hospital and as medical officer of the local provident dispensary.

Dr. Latimer also took a great interest in the civic welfare of Swansea where he was a member of the town council, a justice of the peace, and a member of the old school board.

In 1912 Dr. Latimer retired from practice and took up his residence in Tunbridge Wells, when he soon showed his keen interest in municipal affairs. He was elected to the town council in 1914, becoming Mayor in 1919–20, and deputy Mayor in 1920–21. During his seven years on the council he took an active and prominent part in the work of many committees, while for a time he was a member of the District Education Board. During the war he was chairman of the local Medical War Committee, and in 1918 was employed by the Ministry of National Service as a member of a Travelling Medical Board for the purpose of examining medical men for the army. As chairman of the Surgical Aid Society, and as one of the lecturers and examiners of the St. John Ambulance Brigade his services were greatly appreciated. He also served on the committees of the Natural History and Philosophical Society and the Rescue and Preventive Society.

One of the officers of the British Medical Association writes of him: "During the past ten years I have only occasionally met Dr. Latimer, whose loss his old friends deeply deplore, but between 1903 and 1913 I saw a great deal of him, constantly worked with him, and developed a great respect and affection for him. He had a very attractive personality and was an excellent speaker. He was one of the men who held strongly by Bacon's saying that 'Every man is a debtor to his profession,' a saying which he often quoted and certainly did his best to exemplify in his life. He gave up not only his leisure but much of the time he might well have been spending profitably in his practice in the service of his fellows, and it is due to his colleagues at Swansea to say that they were always grateful to him for it. Latimer was an excellent example of the good general practitioner who believed that he had a duty not only to his patients but to his fellow practitioners, and practised what he believed."

Dr. Latimer was a man of wide culture and reading, and a polished speaker. His contributions to medical literature were few and weighty: among them a study in our own columns of fibroid phthisis in copper workers. He is survived by his widow, his only son having been killed in the war.

THE LATE SIR JOHN TWEEDY.

IN an obituary notice of the late Sir John Tweedy which appeared in THE LANCET last week, while mentioning fully his various public activities, we gave few details of his clinical work. We now supplement our notice with an account of his ophthalmological work which has been sent to us by one of his pupils and colleagues.

"Probably Tweedy's most valuable contribution to ophthalmology was his demonstration that immature cataracts might be safely extracted. Such cataracts were left severely alone, as experience showed that post-operative inflammation almost invariably followed attempts at their removal. The procedure he adopted was to open the capsule at its periphery and not on its anterior face, thereby preventing the lens matter, which of necessity was left behind, from irritating the iris. He practised this method for many years, until with the advance of knowledge the correct explanation of the cause of post-operative inflammation rendered it unnecessary; but the important point is that he demonstrated the feasibility of removing immature cataracts, and his example was quickly followed with the result that the period of incapacity in such cases has been enormously diminished. Another important contribution was that, instead of adopting uniform treatment for all cases of hard eyeball, he pointed out the importance of ascertaining the precise physical condition causing the increased tension in such cases, and having found it, he removed it if possible. Thus, in those difficult cases of cyclitis with increased tension, he advised repeated paracenteses of the anterior chamber, using an extra broad needle for the purpose.

"He was one of the first, if not the first, of the Moorfield surgeons to protest against indiscriminate tenotomy in cases of internal strabismus, pointing out that the rational procedure was by correction of the hypermetropia combined with orthoptic treatment; he rarely or never did a simple tenotomy. But, on the other hand, he described in THE LANCET March 22nd, 1884, a method of advancement which became the usual operation practised at the hospital. The cosmetic results of the operation in his hands, in cases of secondary divergence, were extraordinarily good, although he employed no fancy method of suturing the tendon. Conical cornea was another subject which interested him, and he thought the explanation of the condition was to be sought in some error of development. He treated the condition by cauterising the apex of the cone, and was very insistent on the necessity of making a complete perforation of the cornea. Tweedy's name occurs in most text-books of to-day as advocating the value of quinine lotion in the treatment of diphtheritic conjunctivitis. This was suggested many years before the discovery of the bacillus of diphtheria. He held the view which was not the accepted one at the time, that the diphtheritic process was a local infection, and with the removal of the latter, the general symptoms would disappear. The effect of the fifth nerve on the nutrition of the cornea was a subject which also interested him much. In addition to the obvious connexion of ophthalmic herpes with corneal lesions, he explained similar lesions of the cornea, unaccompanied by skin eruptions, as probably being due to changes in the ophthalmic nerve or Gasserian ganglion, such changes being in his opinion irritative and not paralytic. These ideas were formed long before the removal of the Gasserian ganglion directed attention to the subject."

In THE LANCET in 1888 (see THE LANCET, 1888, vol. i., p. 966) Tweedy wrote on the extraction of immature cataract and gave a full description of the first case where he performed the operation some eight years previously and with perfect success, since which operation, he said, "I have rarely refused to extract a cataract, no matter how immature, whenever both eyes were so affected that the patient was unable to earn his livelihood; and I have operated on such cases almost as often as they presented themselves." This pioneer patient was a compositor, and a few weeks after a prompt recovery was reading "brilliant" type fluently with suitable glasses.

Any notes of Tweedy's ophthalmic work would be incomplete without a reference to his robust faith in the value of internal medication. His therapeutic were not empirical, or at any rate he could always give a reason why he was using a drug in a particular case. Perhaps the greatest tribute of all to Tweedy's work as an ophthalmologist is to be found in the wide view he took of the subject, the result of his philosophic and well-stored mind.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

PARLIAMENT was opened by the King in person on Tuesday last. Contrary to expectation the speech from the Throne contained no reference to health insurance proposals. The main features, so far as home politics are concerned, were that the local authorities were being approached with a view to increased activity under those sections of the Housing Act which enable the working population to become the owners of their houses, and that further measures would be taken to relieve unemployment. H.M. Ministers regretted that the country had not accepted the recent proposals laid before them. Bills would be introduced to improve the position of pre-war pensioners, to amend and consolidate the Factory and Workshop Acts, and to ascertain the costs and profits in connexion with the distribution of milk.

Correspondence.

"Audi alteram partem."

CENTENARY OF THE LANCET.

To the Editor of THE LANCET.

SIR,—The Council of the Royal Society of Medicine desires to take the opportunity—its first meeting since your Centenary—of offering its most cordial congratulations to the Editor and proprietors of THE LANCET on the occasion of its Centenary.

The Council feel that, representing a medical society which celebrated its own centenary in 1905, there is a special appropriateness in congratulating those responsible for the carrying on of their brilliant contemporary. The Society has subscribed to THE LANCET from its first number, and during the hundred years which have passed there has been no addition to its library that has been so eagerly looked forward to and read, and it is not too much to say that its pages have always proved a constant encouragement and support to the advance of medicine in its broadest and best aspects. The Council is delighted to see that under its present management THE LANCET has begun its second century with every prospect of carrying on, so that a hundred years hence their successors may be congratulated on having proved themselves worthy in every respect of their founder and their predecessors.

Yours very truly,

W. HALE-WHITE,
1, Wimpole-street, W., Jan. 8th, 1924. President.

THE AURICULAR BEAT.

To the Editor of THE LANCET.

SIR,—I have read the article by Dr. A. J. S. Pinchin and Dr. S. R. Gloyne in your issue of Jan. 12th with much interest, but I do not understand what is meant when they state "At the apex of the heart the auricular beats . . . could be heard as loud regular *beats* . . ." (the italics are mine). The first sound of the heart has been assumed to be due to the contraction of the ventricular muscle as well as to the closing of the mitral valves, but of late it has been recognised that muscular contraction produces no sound. Does the closing of these valves, if they produce a sound, give rise to the ventricular or auricular "beat"? At the post-mortem examination there was found 5 ounces of fluid in the pericardium, and the movements of this increased quantity are, I venture to think, sufficient to account for any added sounds. It is not recorded whether there was any negative pressure intra-pericardially. In such cases the negative pressure has generally disappeared and the fluid movements are consequently less restrained and give rise to more sounds.

I am, Sir, yours faithfully,

Swansea, Jan. 15th, 1924. G. ARBOUR STEPHENS.

PROF. WHARTON JONES AND THE LATE SIR JOHN TWEEDY.

To the Editor of THE LANCET.

SIR,—I consulted Sir John Tweedy for the first time in 1883 or thereabouts, and on that and another occasion had to be insistent before I could prevail upon him to accept a fee. I should like to add to the names of the eminent staff of University College Hospital at the time when he became a medical student the name of Thomas Wharton Jones, who was held in affectionate esteem by Sir John Tweedy, as well as by the famous Professor Huxley, who had been his pupil and who is reported to have said of him with emphasis "He taught me everything." It is on record that Wharton Jones described Sir John Tweedy as "my best ophthalmic pupil," while Sir John Tweedy, in the obituary notice of his late master, written for THE LANCET, gave full expression to an intention to keep green the memory of a life-long and devoted student of science.

I am, Sir, yours faithfully,

Eastbourne, Jan. 14th, 1924. P. G. CAWLEY.

MEMORIAL TO THE LATE DR. WALLACE BEATTY.

To the Editor of THE LANCET.

SIR,—Past students and friends of the late Dr. Wallace Beatty may be interested to learn that a memorial fund has been opened at the Adelaide Hospital, Dublin, to perpetuate his memory. The hon. treasurer of the committee is Mr. W. Hogg, Fintragh, Shrewsbury-road, Dublin, by whom subscriptions will be gladly received.

I am, Sir, yours faithfully,

Dublin, Jan. 13th, 1924. W. G. HARVEY.

LIVERPOOL MEDICAL INSTITUTION.

To the Editor of THE LANCET.

SIR,—In your report of a paper read by me before this Institution on Dec. 20th, I am stated to have referred to the use of Hewitt's airway. This is not so. The airway I use is that designed by Mr. Blair Bell of Liverpool, a woodcut of which appeared in his text-book on gynæcology many years ago; this particular airway is shown in Dr. Silk's handbook on modern anæsthetics erroneously as Hewitt's. Mr. Blair Bell's latest modification is, I think, an improvement; it is made of copper, the metal tube being divided into five channels so that the respired air is in consequence kept at a higher temperature after the manner of the turbinate bones.

I am, Sir, yours faithfully,

Liverpool, Jan. 11th, 1924. H. H. L. PATCH.

Medical News.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—At a meeting of the Council held on Jan. 10th, Sir John Bland-Sutton, the President, in the chair, the undermentioned diplomas were conferred (in conjunction with the Royal College of Physicians of London) upon the following candidates:—

DIPLOMA IN PUBLIC HEALTH.

E. Benjamin, Bombay and King's Coll.; Florence Bentham, St. Mary's and King's Coll.; M. L. Bery, Manchester; F. J. Darbyshire, Westminster and Royal Inst. Public Health; May C. Ferguson, Dublin and Royal Inst. Public Health; J. M. Ghosh, Calcutta and Univ. Coll.; M. R. Goverdhan, Bombay and Royal Inst. Public Health; Eleanor Harse, Royal Free and Univ. Coll.; E. C. Holtom, Haslar and Univ. Coll.; I. Lewis, Univ. Coll.; R. C. Lightwood, King's Coll.; W. S. McGillivray, Aberdeen and Univ. Coll.; R. H. Parry, Middlesex; H. C. G. Pedler, Univ. Coll.; M. K. G. Pillai, London and Royal Inst. Public Health; Ruth W. Plimsoll, St. Mary's and Univ. Coll.; J. Reid, Cork and Royal Inst. Public Health; P. M. Rivaz, Durham and Royal Inst. Public Health; C. Ross, Glasgow; Effie F. A. Samter, Manchester and Univ. Coll.; N. S. Sethi, Punjab and Univ. Coll.; R. W. G. Stewart, Belfast and Naval Med. Sch., Greenwich; M. L. Sutcliffe, Univ. Coll.; I. S. Thomson, Aberdeen and Royal Inst. Public Health; J. R. Tibbles, Aberdeen and Univ. Coll.; J. Whitby, Middlesex and Royal Inst. Public Health; and S. A. Withers, Univ. Coll.

DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.

Y. A. N. Barrada, P. N. Basu, M. G. Bhandari, H. Das, W. K. Dunscombe, A. A. Hearne, H. B. Lee, G. R. McRobert, P. S. Mills, W. L. Paterson, P. S. Slewyn-Clarke, T. S. Tirumurti, H. S. Watters, C. L. Wilmoth, and A. D. Wright. (All these candidates studied at the London School of Tropical Medicine.)

DIPLOMA IN PSYCHOLOGICAL MEDICINE.

D. R. Alexander, F. G. L. Barnes, J. D. Dyson, A. F. Grimbly, H. D. Hayes, W. J. Lascelles, D. B. M. Lothian, E. E. Pittman, and J. Roy.

DIPLOMA IN LARYNGOLOGY AND OTOLOGY.

J. B. Horgan and W. Wilson.

UNIVERSITY OF LONDON.—A course of three lectures on the Treatment of Contracted Pelvis will be given at the London (R.F.H.) School of Medicine for Women (Hunter-street, Brunswick-square, W.C.) by Dr. Gibbon Fitzgibbon, on Jan. 29th, 30th, and 31st. At the first lecture the chair will be taken by Dr. J. S. Fairbairn. A course of four lectures on Respiratory Exchanges will be given by Prof. Winifred Cullis at the same place on Jan. 24th and 31st, Feb. 7th and 14th, at 5 P.M. Attendance at this course is recognised in connexion with the B.Sc. (Honours) Degree in Physiology. Admission to all these lectures is free.

A NEW edition of Prof. Hugh MacLean's "Modern Methods in the Diagnosis and Treatment of Glycosuria and Diabetes" (Constable and Co.) is announced for early publication.

MANCHESTER CLINICAL SOCIETY.—A lecture will be given in the Medical School, University of Manchester, on Thursday, Jan. 24th, at 4.30 P.M., by Sir Thomas Horder, entitled Medicine and Old Ethics.

A MEMOIR of William and John Hunter, by George C. Peachey, to be published in February, will contain six portraits and a sketch of the early teaching of anatomy in England to 1746, and will throw new light upon William Hunter's association with the Society of Navy Surgeons and upon John Hunter's army career.

TUBERCULOSIS SOCIETY.—A meeting of this society will be held to-day, Friday, Jan. 18th, at the Margaret-street Hospital, Margaret-street, London, W. 1, at 8 P.M., when Dr. A. S. MacNalty will read a paper on Tuberculosis Work in England. After the paper the London County Council Scheme for Post-graduate Study for London Tuberculosis Officers will be discussed.

ROYAL SANITARY INSTITUTE.—An introductory lecture to this term's courses of lectures and demonstrations will be delivered by Dr. Charles Porter on Jan. 28th at 5.30 P.M. (admission free). The course for sanitary officers will be delivered on the 29th, that for meat and food inspectors on Feb. 8th, and the course for health visitors and child welfare workers on Feb. 4th. Further information can be obtained from the Director and Secretary, Mr. E. White Wallis, at the offices of the Institute, 90, Buckingham Palace-road, London, S.W. 1.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—During the month of February a four weeks' course in Children's Diseases will be given by the members of the staff at the four following institutions: Paddington Green Children's Hospital, Royal Waterloo Hospital for Children and Women, Victoria Hospital for Children, and the "Children's Clinic" at the Western General Dispensary. The course will embrace lectures and clinical demonstrations on Medical and Surgical Diseases of Children and also the special departments, including dermatology, nose and throat, diseases of the eye, and clinical laboratory demonstrations. As already announced, a special intensive course is being held at the North-East London Post-Graduate College, Prince of Wales's General Hospital, Tottenham, N. 15, from Feb. 4th to Feb. 16th. A special course in ophthalmology will be given at the Central London Ophthalmic Hospital, Judd-street, from Jan. 28th to Feb. 22nd. The course will consist of clinical lectures and demonstrations, and include the use of the ophthalmoscope, &c. Further particulars and copies of the syllabus for all these courses can be obtained from the Secretary to the Fellowship at No. 1, Wimpole-street, London, W. 1.

DONATIONS AND BEQUESTS.—The late Mr. George Frederick Milnthorp left by will £1000 to the Doncaster Royal Infirmary and Dispensary.—By will the late Mrs. Emily Gertrude Pye-Smith, widow of Dr. Philip Henry Pye-Smith, among other bequests, left £1000 to the Governors of Guy's Hospital to endow a bed to be called the "Dr. Pye-Smith Bed," and to the Royal College of Physicians her late husband's gold medals.—Under the will of the late Mr. William Thomas Rushton, the testator left, among other bequests, £250 each to the Queen's Hospital, Birmingham, and the Birmingham General Hospital; £200 each to the Birmingham Deaf and Dumb Institution; the General Institution for the Blind, Carpenter-road, Edgbaston; the Birmingham and Midland Ear and Throat Hospital; the Birmingham and Midland Hospital for Women; the Birmingham Eye Hospital; the Royal Orthopædic and Spinal Hospital; £100 each to the Birmingham Dental Hospital; the Birmingham and District Cripples Union; the Women's Hospital, Birmingham; the Birmingham Maternity Hospital; the Taylor Memorial Home of Rest, Sparkhill, Birmingham; the Bromsgrove Cottage Hospital; the Blackwell Sanatorium; and St. Dunstan's Home for Blinded Soldiers, London.

LECTURES on (1) Headache, (2) Rheumatism, (3) Gout, and (4) Obesity will be delivered by Sir Robert Armstrong-Jones at Gresham College, Basinghall-street, London, E.C., on Jan. 29th, 30th, 31st, and Feb. 1st respectively at 6 P.M. Admission is free.

IN the recent New Year Honours Dr. Alexander Hendry, M.V.O., of Ballater, was created a Commander of the Royal Victorian Order. Dr. Hendry is well known in Upper Deeside as a successful medical practitioner and also represents that district in the Aberdeenshire Education Authority. He is also a justice of the peace for the county and a member of the Deeside District Licensing Court.

KINGSEAT MENTAL HOSPITAL.—The Aberdeen City District Board of Control met on Jan. 8th to discuss the proposed extension of the hospital. Mr. Thomas Mitchell presided. Approval was given to erect additional villas at Kingseat Asylum and increased accommodation in the nurses' home. The estimate of cost was £43,000. The sketch of the plans suggested by the consulting architect to be first brought before the district board for adoption.

MEDICAL PRAYER UNION.—A meeting will be held at the London (R.F.H.) School of Medicine for Women, Hunter-street, Brunswick-square, London, W.C., on Jan. 24th. The Medical School will be open for inspection at 4.30 P.M. and the meeting will begin at 5.30 P.M. when an address will be given by Dr. Douglas Adam. Those who intend to be present are asked to inform Dr. Tom Jays, the Hon. Secretary, Livingstone College, Leyton, E. 10.

PUBLIC DENTAL SERVICE ASSOCIATION.—The fifth annual dinner of the East Lancashire and East Cheshire Branch of this Association was held recently in Manchester. The chairman, Mr. P. I. Wigoder, said that it was estimated that from 20 to 40 per cent. of the children attending schools were suffering from grave dental defects, and that 70 per cent. needed some dental treatment. In Manchester only four school clinics had been established instead of the 18 originally proposed. It was, however, with the question of adult dental disease that the Association was chiefly concerned, as it was estimated that half of the ill-health of the industrial classes was due, directly or indirectly, to defective teeth. At present the Association could only cope with this problem by coöperating with the approved societies who were making provision for dental treatment out of their surplus funds. The members of the Association were prepared to give their services to the societies on an agreed scale of remuneration. Mr. Walter Davies, chairman of the Manchester Insurance Committee, expressed the opinion that the State would never secure the measure of public health it aimed at until it made provision for using the services of dentists as it had made for using the services of the doctors. Provision for dental treatment at present could only be made by approved societies out of their surplus funds. It was hoped that at no distant date dental treatment would be included as one of the general benefits under the Act. This would mean that in Manchester half the population would be placed automatically in the hands of the dentists.

EDUCATIONAL TOURS FOR MEDICAL OFFICIALS.—By request of the Ministry of Health, the Society of Medical Officers of Health has undertaken the selection of representatives from the United Kingdom to take part in the interchanges of health officers organised by the Health Section of the League of Nations. For a course in general health administration to be held in the Netherlands (April 24th–May 30th) the Society has nominated Dr. A. T. Nankivell, M.O.H. of Hornsey, and Dr. T. S. McIntosh, M.O.H. of the Hendon Urban District. For a similar course in Denmark (June 1st–July 14th) the British representatives will be Dr. F. T. H. Wood, M.O.H. of Bootle, and a medical officer of the Ministry of Health. A third course in general health administration to be held in Switzerland (August 10th–Sept. 20th) will be attended by Dr. A. B. McMaster, M.O.H. of Dover, and Dr. W. H. Davison, Assistant M.O.H. of Birmingham. The Society has also nominated Dr. W. H. Dickinson, of the Newcastle-on-Tyne Health Department, for a course in anti-tuberculosis work to be held in Austria, France, Hungary, Belgium, Switzerland, and other European countries from February 6th to April 30th. Dr. Raymond Gamlin, senior assistant school medical officer at Liverpool, has been selected for a European course in school medical work the dates for which are not yet fixed. All the nominations are subject to the consent of local authorities to grant the necessary leave of absence. The Health Section of the League of Nations is enabled to defray the expenses of the courses by a generous grant from the Rockefeller Trustees.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear it if reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY, Burlington House, Piccadilly, W.
THURSDAY, Jan. 24th, at 4.30 P.M.—*Papers to be read*:—H. G. Cannon: On the Development of an Estherid Crustacean. (Communicated by Prof. E. W. MacBride.)
Papers to be read in title only:—C. Shearer: The Oxygen Consumption Rate of Parts of the Chick Embryo and Fragments of the Earthworm. N. Annandale, D.Sc.: The Evolution of the Shell-Sculpture in Freshwater Snails of the Family Viviparidæ. (Communicated by Lieut.-Colonel A. Alcock.) Prof. B. Sahni: *Tmesipteris Vieillardi* Dangeard. An erect Terrestrial species from New Caledonia. (Communicated by Prof. A. C. Seward.) P. A. Buxton: Heat, Moisture, and Animal Life in Deserts. (Communicated by Prof. J. S. Gardiner.) A. W. Bellamy and Prof. C. M. Child: Susceptibility in Amphibian Development. (Communicated by Prof. E. W. MacBride.)

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, Jan. 21st.

SPECIAL DISCUSSION: at 5 P.M.
On the Grading of the Population from the Point of View of Bodily Fitness, to be opened by Air-Commodore David Munro, R.A.F., followed by Sir Arthur Keith, Sir Duncan Rhind, Dr. John Wallace, and others.

Wednesday, Jan. 23rd.

COMPARATIVE MEDICINE: at 5 P.M.
Paper:
Prof. E. Mellanby: Diseases of Nutrition in Animals. The paper will be followed by a discussion, in which the following will take part: Prof. J. B. Buxton, Miss Harriette Chick, Mr. Henry Gray, Mr. G. H. Livesey, Prof. C. J. Martin, and Prof. M. S. Pembrey.

Friday, Jan. 25th.

STUDY OF DISEASE IN CHILDREN: at 5 P.M. (Cases at 4.30 P.M.)
Cases:
Dr. Geoffrey Evans: Case of Interstitial Nephritis in a Child.
Dr. C. Worster-Drought: Juvenile Tabes Dorsalis in a girl aged 10 years.
Dr. W. M. Feldman: Case for Diagnosis.
Mr. O. L. Addison: Specimen (the Spleen) of a Case of "Gaucher Splenomegaly."
Other cases will be shown.

EPIDEMIOLOGY AND STATE MEDICINE: at 8 P.M.
Paper:
Dr. J. Kerr: Refuse Disposal in Relation to the Enteric Group of Diseases.

ROYAL INSTITUTION OF GREAT BRITAIN, 21, Albemarle-street, W. 1.
TUESDAY, Jan. 22nd.—5.15 P.M., Dr. W. E. Dixon: Drug Addictions. (Lecture II.)

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.
WEDNESDAY, Jan. 23rd.—4 P.M., Dr. G. L. Cox: Organisation of County Schemes for Prevention of Tuberculosis.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.
MONDAY, Jan. 21st to FRIDAY, Jan. 25th.—NORTH-EASTERN FEVER HOSPITAL. Wed. and Sat., 11 A.M., Dr. Frederic Thomson: Diagnosis and Treatment of the Acute Infectious Diseases.—ST. PETER'S HOSPITAL FOR STONE. Mon., 2 P.M., Mr. Andrews: Injuries of the Urinary Organs: Tues., 2 P.M., Mr. Joly: Urinary Calculi and Calculous Disease; Wed., 2 P.M., Mr. Morson: Tumours of the Urinary Tract; Thurs., 2 P.M., Mr. F. J. F. Barrington: Non-tuberculous Infections of the Urinary Tract; Fri., 2 P.M., Sir John Thomson-Walker: Urinary Obstruction; Sat., 2 P.M., Mr. Harkness: Urethritis in the Male.—WEST END HOSPITAL FOR NERVOUS DISEASES, at 73, Welbeck-street, W. 1. Mon., 1.30 P.M., Dr. Harry Campbell: Cerebral Tumour, Hemiplegia; Tues., 5 P.M., Dr. Ridley Prentice: The Significance of Absent Knee- and Ankle-Jerks; Fri., 5 P.M., Dr. C. Worster-Drought: Neurosyphilis, Diagnosis and Treatment.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn-fields, W.C.
MONDAY, Jan. 21st.—5 P.M., Prof. St. Leger Brockman: The Problem of Drainage in Acute Appendicitis.
WEDNESDAY.—5 P.M., Prof. R. Handfield-Jones: Retro-peritoneal Cysts, their Pathology, Diagnoses, and Treatment.
FRIDAY.—5 P.M., Prof. S. Forsdike: Cancer of the Cervix.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.
MONDAY, Jan. 21st.—10 A.M., Mr. Maingot: Surgical Pathology. 12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Mr. Simson: Diseases of Women.
TUESDAY.—12 noon, Dr. Burrell: Chest Cases. 2 P.M., Mr. Sinclair: Surgical Out-patients. 2.30 P.M., Mr. Tyrrell Gray: Surgical Wards.
WEDNESDAY.—10 A.M., Dr. Saunders: Medical Diseases of Children. 12.15 P.M., Dr. Burnford: Medical Pathology. 2.30 P.M., Mr. Donald Armour: Surgical Wards.
THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Dept. 2 P.M., Dr. Scott Pinchin: Medical Out-patients. 2 P.M., Mr. MacDonald: Genito-Urinary Dept.
FRIDAY.—10.30 A.M., Dr. Pritchard: Medical Wards. 12 noon, Mr. Endean: Venereal Diseases. 2 P.M., Mr. Banks-Davis: Throat, Nose and Ear Dept.
SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose and Ear.
Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.
THURSDAY, Jan. 24th.—4 P.M., Dr. Nabarro: Cerebro-spinal Fluid and its Value in Diagnosis.

QUEEN CHARLOTTE'S LYING-IN HOSPITAL, Marylebone-road, N.W.
THURSDAY, Jan. 24th.—5 P.M., Mr. Banister: Late Manifestations of Puerperal Sepsis.

CANCER HOSPITAL, Kensington, S.W.
WEDNESDAY, Jan. 23rd.—4.30 P.M., Mr. C. Rowntree: Radium and its Surgical Uses.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.
TUESDAY, Jan. 22nd.—5 P.M., Dr. H. Davis: Dermatitis Artefacta.
THURSDAY.—5 P.M., Dr. H. MacCormac: Animal Parasites (Chesterfield Lecture).

ST. MARY'S HOSPITALS, MANCHESTER, POST-GRADUATE LECTURES (at Whitworth-street West Branch).
FRIDAY, Jan. 25th.—4.30 P.M., Mr. Morley: Pyloric Stenosis in Infancy.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES. (At 3.30 P.M.)
MONDAY, Jan. 21st.—(At the Children's Hospital.) Mr. Leathart: Reasons for Removal of Tonsils and Adenoids.
TUESDAY.—(At the Southern Hospital.) Dr. Frank H. Barendt: Scaly Eruptions.
WEDNESDAY.—(At the Northern Hospital.) Dr. Pemberton: Treatment of Diabetes Mellitus.
THURSDAY.—(At the Stanley Hospital.) Dr. Wadsworth: Artificial Pneumothorax.
FRIDAY.—(At the Royal Infirmary.) Prof. Glynn: Some Points in Clinical Pathology.

UNIVERSITY OF SHEFFIELD POST-GRADUATE LECTURES.
FRIDAY, Jan. 25th.—3.30 P.M. (At the Royal Infirmary.) Dr. Yates: Psychotherapy.

Appointments.

BLACKABY, E. J., M.R.C.S., L.R.C.P. Lond., has been appointed House Surgeon to the Royal Infirmary, Sunderland.
COUNIHAN, J. H., M.B., B.Ch. Dub., Coroner for North County Clare.
COUTTS, N. M., M.B., B.S. Lond., House Surgeon, Children's Hospital, Sunderland.
FORD, R. K., M.B., B.S. Lond., Medical Officer of the Poor-law Institution and Infirmary and the Children's Homes, Darlington.
FORWARD, F. E., F.R.C.S. Eng., Medical Officer of Parkhurst Prison.
GRANT, MARJORIE, M.B., Ch.B. Manch., and KING, MARJORIE,, M.B., Ch.B. Edin., Assistant School Medical Officers for Cheshire.
JOHNSON, W. P. S., M.D., Ch.B. Edin., Medical Officer to the County of Fife Venereal Diseases Joint Committee.
WOOD, J. W., M.B., Ch.B. Aberd., Honorary Aural Surgeon to the Eye and Ear Hospital, Tunbridge Wells.
Certifying Surgeons under the Factory and Workshop Acts: RAYNER, E. C., M.R.C.S., L.R.C.P. Lond. (Dulverton); COURTNEY, J. M., M.R.C.S., L.R.C.P. Lond. (Lynton); and SMITH, C. R., M.B., B.S. Durh. (Beccles).

Vacancies.

For further information refer to the advertisement columns.

Birmingham, Queen's Hospital.—P. to Out-patients. £50.
Birmingham Union, Dudley-road Hospital.—Res. P. £650. Also Res. Asst. M.O. £300.
Bolton Infirmary and Dispensary.—Asst. H.S. £100.
Cheshire Joint Sanatorium, Market Drayton, Salop.—Second Asst. M.O. £350.

Chester Royal Infirmary.—Asst. H.S. £150.
City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E.—H.P. £125.
Elizabeth Garrett Anderson Hospital, Euston-road.—Asst. to Clin. Pathologist. £100.
Gloucester, Gloucestershire Royal Infirmary and Eye Institution.—H.S. £175.
Hayward's Heath Hospital.—Hon. Consulting P.
Hemel Hempstead, West Herts Hospital.—R.M.O. £200.
Hospital for Sick Children, Great Ormond-street, W.C.—Cas. O. Also Asst. Pathologist. Each £400.
Hull Royal Infirmary.—Sen. H.S. £200.
Laboratories of Pathology and Public Health, 6, Harley-street, W.—Fourth Asst. Pathologist. £500.
Lancashire County Mental Hospital, Winwick, Warrington.—A.M.O. £432.
Liverpool, Royal Southern Hospital.—Res. Cas. O. £150. Also H.P.'s and H.S.'s. Each £100.
London Lock Hospitals, 283, Harrow-road, W. 9, and 91, Dean-street, W. 1.—Hon. Ophth. S.
Manchester, Royal Children's Hospital, Gartside-street—Asst. M.O. £150.
Manchester Royal Eye Hospital.—H.S.
Manchester Royal Infirmary.—Asst. M.O. in Radiological Dept. £105.
Miller General Hospital for South-East London, Greenwich-road, S.E. 10.—H.P. £150.
Orkney, Parish of Eday.—M.O.
Orpington, Kent, Ministry of Pensions Hospital.—Consultant P. £450.
Penshurst, Kent, Cassel Hospital for Functional Nervous Disorders. Res. M.O. £500.
Plaistow Fever Hospital.—Second Asst. M.O. £200.
Royal Army Medical Corps.—Commissions.
St. Thomas's Hospital Medical School.—Demonstrator of Anatomy. £400.
Salisbury General Infirmary.—Asst. H.S. £150.
Sheffield Royal Hospital.—Cas. O. £150.
South London Hospital for Women, South Side, Clapham Common, S.W. 4.—Asst. S.

The Chief Inspector of Factories, Home Office, London, S.W., announces vacancies at Epsom, Harpenden, and Coniston.

Births, Marriages, and Deaths.

BIRTHS.

BANKS.—On Jan. 8th, at Ty Mawr, Aberdare, the wife of Harry Banks, F.R.C.S., of a daughter.
HODGES.—On Jan. 13th, at Boscombe Court, Boscombe, Hants, the wife of Arthur Noel Hodges, M.D., of a daughter.
WILSON.—On Jan. 6th, at "Stonefield," Blackheath, the wife of Captain Colin Wilson, R.A.M.C., of a daughter.

DEATHS.

LATIMER.—On Jan. 10th, at Oakdale-road, Tunbridge Wells, Henry Arthur Latimer, M.D. (late of Swansea, South Wales), in his 75th year.
MARTIN.—On Jan. 9th, following an operation at a nursing home in London, Henry J. W. Martin, M.R.C.S. Eng., aged 68.
ROPER.—On Jan. 11th, at The Shrubbery, Exeter, of pneumonia, Arthur Charles Roper, F.R.C.S. Edin., J.P., aged 65.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts

THE USE AND ABUSE OF PHYSICAL TREATMENT.[1]

BY JAMES B. MENNELL, M.D., B.C. CAMB.

IN its early days, some 25 years ago, the Chartered Society of Massage and Medical Gymnastics was known as the Incorporated Society of Trained Masseuses. To give an idea of the uphill fight of physical treatment in this country I may say that 15 years ago, when I first began to take an active interest in the subject, a deputation of my fellow house officers at hospital waited upon me to request me not to degrade my profession by studying such a very doubtful branch of medical practice. It seemed then that the best I could hope for our generation was that we should sow the ground for others to reap the harvest, but our work has advanced so rapidly in recent years that I still hope to see physical treatment fully established in the prominent position in the medical armamentarium which it seems to me it should hold. The formation of each of these lecture centres marks a definite step forward in the progress of physical treatment, and I think that nothing can now undo the work of the past.

The uses of physical treatment are, I think, fairly universally admitted, though unfortunately the variety of its uses are still unknown, and still less are its abuses known and realised. Those of us who practise physical treatment are mainly regarded as a last resource; patients come to us when every other known means of helping them has failed to find, even after suffering pain and disability for 20 years, that in physical treatment they are able to secure relief.

Massage as a Curative Agency.

It seems to me futile to try to trace the history of massage back into antiquity; there can be little doubt that the first occasion on which massage was applied to a human limb was the day on which our earliest ancestor began laborious work. Massage is, to all intents and purposes, instinctive not only throughout the human race, but also in a large section of the animal kingdom. Yet I think that the more thoughtful of us realise that the more we see of the use of massage, the less we come to rely on it alone as a curative agency. I do not wish to appear to belittle the value of massage; but it should be used largely as a means to an end, and preferably at the beginning of treatment. Many people labour under the delusion that they possess a supernatural power of healing in their hands; to me this conception is utter balderdash, long experience leading me to regard such people as the most unreliable of the members of their profession.

Putting aside the obvious dangers which beset even a masseur, such as the request for massage in cases of malignant growth, or where thrombosis has occurred, one other danger—psychical, not physical—is all too little realised. It is far easier to rub a disability into a patient's mind than to rub it out of his limb. If 10 minutes' massage is necessary, and 20 minutes' massage is given, surely we convey to the patient's mind the undesirable suggestion that the condition is 100 per cent. more serious than in fact it is.

One masseuse to be avoided, then, is the one who prides herself on giving her full hour of massage to every case, another is the one who sits down and works automatically with her thoughts obviously not on her work. The proficient masseuse should be able at any moment to give a reasoned and intelligent reply to the question, "What are you doing that for, how often have you done it, and how often do you propose to do it in order to secure the fullest physiological result?" This may be an unattainable ideal, but physical treatment must not be blamed for failure to effect a cure if, through lack of adequate instruction, the masseuse is left in ignorance of the exact condition she is called upon to treat. Neither by training, nor, as a rule, by experience, is she a diagnostician.

Instances of Conditions Unaffected by Massage.

In a case of pain in the lower extremity due to sacro-iliac or to lumbo-sacral strain, only by the mercy of Providence can massage possibly be of any service. In brachial neuritis if the pain is due to reflex irritation from fibrositic deposits round the scapula or to adhesions within the shoulder-joint physical treatment applied to the arm is not only useless but liable to increase, rather than decrease, the irritation. It is a comparatively simple matter to explain the massage

[1] An abstract of a lecture delivered on Nov. 20th, 1923, at the opening of the Lecture Centre of the Chartered Society of Massage and Medical Gymnastics at Eastbourne.

treatment of any individual case to any reasonably intelligent and skilled individual, but it requires a very unusual amount of both skill and experience to be able to prescribe the correct form of treatment for every case.

Massage treatment may be rendered not only futile, but definitely harmful; not infrequently, more harm than good is done by this treatment in cases of infantile paralysis and other forms of flaccid paralysis. A common phrase, long used amongst those who practise massage, is that of "working up a muscle"—which means, presumably, that as a direct result of massage treatment, muscle strength can be built up. In my opinion the latter possibility is a mere delusion, probably arising from the following type of case: A patient after, say, a severe attack of typhoid, may have very considerable wasting of the muscles; massage is ordered, and activity may shortly seem to return, with increase of muscle bulk. I submit that this increase of muscle is a secondary, not a primary, result. The massage produces a sense of well-being and returned vitality; the resulting desire for spontaneous movement enables the patient to start along the path of recuperation, but I am convinced that no strength was ever built up as the direct result of massage. Massage assists the circulation in the removal of waste products, and maintains it through the part, but cannot possibly secure one single voluntary contraction.

In the cases of nerve injury encountered in such numbers during the war, some of the nerve operations were complete failures in every respect. Recovery was not only delayed, but also permanently impossible to effect by physical or any other means. Yet amongst cases where nerve suture was successful were some presenting an apparently amazing rapidity of recovery; other cases are recorded where recovery has been regarded as so hopeless that a tendon transplantation has been performed, whilst a few weeks later muscle recovery has taken place in the paralysed muscle. I believe, however, that one of the curses attendant upon those who suffer from a flaccid paralysis is the somewhat widespread belief—amongst those who practise physical treatment and others—that voluntary action in a paralysed muscle cannot be secured until a faradic response can be elicited. I am absolutely convinced in my own mind of the fallacy of this belief, but it generally holds good if the person to whom the care of the patient is entrusted is not expert in muscle training; for a psychical block to voluntary impulses, no less than a physical obstruction, can exist in a nerve connexion.

Muscle Training.

Muscle training is an art apart; it calls for an intimate knowledge of anatomy, and of muscle function, which is quite another subject. The prime mover must be held distinct from the synergist—direct or static, and the action of the antagonists must be fully known. Then, too, there are some dozen laws to be regarded in all muscle training, and neglect of one transforms success into failure. It is perhaps in muscle training that expert skill shows itself more plainly than in any other branch of physical treatment, except perhaps in the treatment of the more serious cases of recent injury.

Following on the same line of thought it is, of course, a matter of common knowledge that the apparent paralysis present after an attack of infantile paralysis is far more extensive than is justified by the actual lesion. Nearly always is it possible to hope for some recovery when the patient is seen for the first time; yet of this I am sure, that a certain amount of recovery, though possible, only too often fails to take place merely because the paralysis still continues to exist in the patient's mind. He who holds the faith that massage can "work up a muscle," or that electrical stimulation of a muscle is going to cure his patient, places his faith in a broken reed, and perhaps the greatest danger in electrical treatment of a muscle is that it may enforce upon the patient's mind the idea that his muscle can only move in response to electrical stimulation. When we remember that the earliest contractions can only be elicited in certain positions and under certain circumstances, I think it is possible to realise how recovery can be postponed, not only through lack of physical treatment, but perhaps directly because of lack of skill in the administration thereof.

The surgeon can render recovery possible, but the recovery in the end depends on the patient and his own volition.

Then let us consider the treatment of a patient after injury or operation. To some, perhaps, I am known as the English disciple of Just Lucas-Championnière; I have probably been responsible for the treatment of 500 or 600 cases of fracture of the lower end of the humerus in children; in all of them I have used massage and mobilisation from the very outset, and never since the earliest days have I had cause to regret it. Yet throughout this country and in America the general belief is that this fracture should not be so treated. Lack of knowledge of manipulative dexterity and technique is the basis on which this belief is built. I was once complimented by an eminent surgeon on the "moral control" that I had over the children who had sustained fracture, and who were receiving treatment in my department; I pointed out that what he had witnessed was the result of manipulative dexterity on the part of my staff.

With regard to the treatment of children with fractures near the elbow-joint, if such treatment is painful the patient is suffering from abuse, not from use, of treatment. Rarely, if ever, do I allow massage of any sort to be administered to these patients after the first few days; and, as regards mobilisation, any movement administered during the first two weeks must be passive in the true sense of the word—in other words, it must be administered only while the muscles throughout the limb are in a condition of complete relaxation.

In a vast number of cases physical treatment is applied and found wanting. In those complaints, known variously as brachial neuritis, lumbago, and sciatica, physical treatment is often meted out as a last resource; massage is applied, and often the patient is worse as a result. Ionization is given, or perhaps diathermy, radiant heat, or light treatment, and the patient is comforted but not cured. Yet physical treatment properly applied is frequently the one and only curative agency. The more I see of these cases the less I believe in the existence as a general rule of a true neuritis. Do not think for one moment that I deny the existence of a true sciatica; I am sure, however, that it is a condition very rare when compared with others capable of producing the most intense pain along the course of any nerve in the lower extremity. The one cardinal sign of true sciatica—namely, pain when the hip is flexed upon the trunk and the knee extended—is accepted as diagnostic if pain is produced; bad luck has it that this, too, is one of the cardinal signs of a far more common condition often producing nearly identical symptoms—namely, sacro-iliac strain. Is it any wonder, therefore, that physical treatment for sciatica and lumbago fails us when the only possible hope of cure or even of relief rests either in manipulation of the joint or in affording it support with a belt?

Fibrositic Deposits causing Sciatica or Neuritis.

Another fertile source of so-called sciatica or neuritis is the presence of fibrositic deposits, capable of causing the most intense reflex irritation along the course of various nerve trunks. We know little enough about these fibrositic indurations, but of their existence I am absolutely firmly convinced. I am slowly coming to realise that in certain positions these deposits are capable of causing referred pain down the course of definite nerve trunks. Such deposits are (very occasionally) found under the scalp, then in the occipital region, then at any point in the muscle mass between the cervical spinous processes and the transverse processes and, less frequently, just in front of the transverse processes. Here, however, I would add one word of warning. It has often been my lot to be told that a patient has an intensely sensitive spot which no amount of friction has succeeded in dispersing, and on examination this has not surprised me, as I know of no means by which the tubercles of the transverse processes of the vertebræ can be removed short of operation. Then there are two favourite spots for these deposits around the scapula. One has been mentioned, a second is to be found by placing the hand of the affected side upon the opposite shoulder, and then pressing deeply against the chest wall just opposite the base of the spine of the scapula. They occur, too, in a most inaccessible position—namely, between the body of the scapula and the chest wall. Fortunately the condition is not very common, but when it does occur it is capable of producing the most intense pain throughout the upper extremity. It can only be dealt with by exerting deep pressure on the scapula against the chest wall, while the former, so to speak, is ground firmly against the latter. Then they can occur in both supra- and infra-spinatus about the level of the acromio-clavicular joint, but in this position they must not, of course, be confused with arthritis or strain of this joint. Passing down the arm, they are to be found, comparatively rarely however, near the insertion of the deltoid, the origin of brachialis anticus, in front of the condyles of the humerus, and I have often been told that one has been discovered on deep pressure on the outer side of the forearm near the head of the radius. I question the existence of this spot, as when I have examined it, it is one of the normally painful spots on deep pressure. Then we come to two more painful spots which are a fertile source of so-called "writer's cramp." One is a nodal thickening perhaps in, perhaps near, the median nerve about a hand's breadth above the wrist-joint, and the other, apparently a true fibrositic deposit, just distal to and slightly internal to the trapezium in the palm.

Returning to the trunk, one spot occurring with remarkable frequency in patients suffering from brachial neuritis is in the third intercostal space in front somewhere about the nipple line. Unless this is dealt with effectively many a

case of brachial neuritis will fail to clear up. Deposits capable of causing referred pain are also found anywhere along the line which represents the outer limit of the erector spinæ, and a particularly unenviable lot is that of the patient where one of these spots is discovered in the angle formed by this line and the lower border of the twelfth rib. I think you will frequently find that this is present in those patients who are able to start off for a walk without a twinge or flicker of pain, and who yet, after going a variable distance, begin to feel intense pain creeping on until they are compelled to sit down and rest after having traversed a comparatively short distance. Around the transverse processes of the first lumbar vertebra we are also liable to discover more of these deposits, though, curiously enough, it would seem that they are not very common in the remainder of the lumbar region until we come to the gluteal region already referred to. Again, it is common for me to be told that a painful spot has been discovered near the junction of the ilium with the sacrum, but experience has taught me that this is indicative of strain of the sacro-iliac joint. I believe deposits here to be very rare. In the gluteal region not only are deposits to be found round the crest of the ilium, but they are also frequently to be found on deep pressure over the edge of the great sacro-sciatic notch. Passing downwards they are comparatively rare until (why, I do not know) we reach the neighbourhood of the knee-joint where two spots can not infrequently be discovered on deep pressure between the heads of the gastrocnemius and the tibia. Occasionally one may be found in the sole of the foot, even if the patient presents no evidence whatever of flat-foot or other cause of strain or trauma. It is not uncommon, I believe, to consider that pain due to a traumatic metatarsalgia which presents pain on pressure can be cured by massage; the latter treatment may ease but can never cure. The moral of all this is simply that physical treatment rightly applied can be curative; wrongly applied, it is not only futile, but capable of inspiring in the patient's mind a feeling of despair which renders him completely incapable of enjoying a life which is so interwoven, apparently without hope, with pain and suffering.

Pain in the Feet.

It is customary to consider that a patient who complains of pain in the feet is making an undue fuss, but the patients who display the greatest gratitude are those whom I am able to relieve in this respect. Manipulation can sometimes do much, but either manipulation or massage can seldom do more than afford very transitory relief. The faradic footbath, on the other hand, is a definite remedial agent, and this, combined with a proper support (hard to secure unless you make it yourself), can, I believe, be relied upon to secure relief until the patient is sufficiently recovered to build up his own muscle strength, and so effect his own recovery. When actual deformity has taken place, it means the permanent use of adequate support. For some time past, however, I have come to the conclusion that unless there are definite arthritic changes in the intertarsal joints, no foot condition is so bad that pain in it cannot be relieved by purely physical means, which, of course, include support. On the other hand, if there is a definite arthritis in a joint such as the subastragaloid joint, as, for instance, after fracture of the os calcis, nothing but fixation of the joint can possibly relieve the pain.

Flat-Foot.

Putting aside the question of footgear, treatment by physical exercises is most commonly prescribed for flat-foot. Here failure in treatment is, I think, due to one of two causes. In the first place, no amount of massage or electrical treatment will ever succeed in loosening joints which have become stiff, for this is essentially the function of manipulative treatment; secondly, no amount of re-education of the muscles which support the arch of the foot can possibly prove effective if the stance and position of the feet in walking remain uncorrected. It is for this reason that I always tell my students that the most important muscle to educate in patients suffering from flat-feet is the quadriceps extensor. Teach your patient to stand with feet parallel and the knees braced back, and to walk with the feet parallel instead of everted, and the success of the other forms of treatment is comparatively certain; whereas, without this special training, failure, or at least relapse, is almost equally certain.

Joint Manipulation.

I believe that during the war a general order was issued prohibiting the manipulative treatment of stiff hands under an anæsthetic after septic gunshot wounds of the upper extremity. And yet we knew full well that these manipulations were being performed by a limited few with the utmost success, though, for the most part, the operation was attended by failure. The manipulative treatment of joints is a special art requiring special study and special skill in execution. With the solitary exception of the hip joint, in few, if any, joints in the whole body is it impossible to perform some definite movement not ordinarily under the patient's voluntary control. Again, movements in joints are by no means always what they seem. Flexion of the finger, for instance, is not a hinge movement, but a gliding movement; with the proximal end of the lateral ligaments as centre and their distal insertion as radius the base of the phalanx describes a circle. If this circle is not described, and if flexion is performed without the sliding movement involved in the circular movement of the base of the phalanx round the head of the proximal bone, severe damage is inevitable.

Mobilisation Treatment.

Performed in the right way, mobilisation treatment may be a potent influence for good; performed in the wrong way it is equally potent for evil. This subject is, of course, mixed up with what is commonly known as the art of bone setting, and the question arises, Is there, or is there not anything whatever in the bone-setter's story of the "little bone" being out of place? The ordinary unqualified practitioner usually attributes pain in a joint to some definite displacement of the bones which enter into the formation of the joint, and claims that the relief which he is at times able to secure is due to a demonstrable reduction of the bony displacement. That minor displacements of bone do, in certain cases, exist, and do cause symptoms, I am firmly convinced. But it is possible, under certain circumstances, for a locking to take place within many of our joints, in spite of the fact that there is no discernible displacement. It is, as a rule, impossible that this locking should be overcome merely by the performance of the ordinary movements which take place in the joint; indeed, the forcible performance of these movements will often do harm rather than good. It is essential, therefore, if the manipulative treatment of joints is to be undertaken at all with any prospect of success, that the manipulator should be acquainted with those movements which take place at joints and which are not under the voluntary control of the patient, and that he should know how to perform them so as to ensure that any locking which may have taken place is undone before he attempts to force the ordinary movements of the joint that are under voluntary control.

Massage and Obstetrics.

Even in the unexpected field of the obstetrical department physical treatment finds its place; it is becoming more and more recognised how advantageous it is for an infant to receive its natural food, at any rate during the earlier months of life. When, however, the supply is running low, we have not by any means universally recognised as yet that in massage we have perhaps the most potent agency of all for restoring the activities of the source of supply. Then, too, as in all medicine and surgery, the highest glory is attained on the preventive side; thus the practice of physical exercise treatment after confinement is valuable.

Massage in Functional Diseases of the Central Nervous System.

In organic disease of the central nervous system it is obvious that, for the most part, physical treatment is the only agency which can materially help, although it can do nothing to cure. In functional nervous disease, however, we have an entirely different story; it is difficult to imagine any treatment more pernicious than massage as a means for curing the hysteric—unless indeed it is used, or rather abused, by transforming it into a form of physical punishment. Surely to apply massage in these cases is simply to back up the conscious against the subconscious; whereas, of course, the only hope of success is the reverse process of backing up the subconscious against the conscious. Anything may be used as a means of conveying a curative suggestion, but massage should not be employed as a remedy for a mental condition. Yet there are three golden rules of treatment which, if they are observed, will render massage treatment for the neurasthenic by far the most potent agent we have at our disposal. They are quite simple: Any tender or hypersensitive point should receive attention last; all of the so-called stimulating movements of massage must be prohibited; otherwise, the nature of the movements performed is absolutely immaterial, provided that they are rhythmical. If these laws are faithfully obeyed, massage is the one sovereign cure for insomnia: disregard them and disaster must follow.

Other rules in the treatment of all cases of recent injury and of other patients where function is to be restored, are these: If as a result of treatment there is any increase of pain, increase of swelling, or decrease of mobility, something has gone wrong, or too much has been done; whereas with decrease of pain, decrease of swelling, and increase of mobility the right road has been attained, and it is safe to proceed along it.

May I close by pointing a moral? Physical treatment is expert work, and should be left only in expert hands if it is to be successful. Do not blame physical treatment if it fails when confided to the untrained practitioner; rather lay the blame at the door of those who, being so ignorant of physical treatment themselves, fail to recognise the high degree of skill which may be required to provide adequate treatment for any individual case. This skill can only be the outcome of prolonged training as a preliminary to experience and practice.

HEALTH SERVICE OF IRAQ (MESOPOTAMIA).

A REPORT by the High Commissioner (Major-General Sir Percy Z. Cox) on the administration and condition of the Iraq for the period from Oct. 1st, 1920, to March 31st, 1922, has been issued as a Parliamentary paper. In the section devoted to health service it is stated that certain dispensaries have been closed, and that the following institutions have been opened (or reopened): civil hospitals at Diwaniyah and Samawah, and civil dispensaries at Baghdad West, Hindiyah Barrage, and Fallujah. Nine British officers on the staff resigned during the period: one, Dr. A. C. Oldham (Ahwaz), died; and five were recruited. Two British nursing sisters resigned; one, Miss E. Kidd (Basrah), died; and 12 were recruited. Five local doctors resigned and eight joined the service. Many of these are part-time officials. Difficulty has always been experienced in getting local doctors to take whole-time appointments. This is due mainly to a shortage of qualified medical practitioners in the large towns, and partly to the disinclination of the Iraqi doctor (usually city bred) to leave his home and serve in an out-station. The institutions of the health service provide a total of 1539 beds for in-patients, in addition to which the railway hospitals provide 99. During the year ending March 31st, 1922, 18,926 in-patients were admitted, of whom 15,582 were discharged and 1223 died; 607,484 out-patients (old and new cases) were treated. The following infectious cases were notified during the year: cerebro-spinal meningitis, 26; plague, 137; small-pox, 475; typhus, 61; chicken-pox, 90; measles, 605; mumps, 92; tuberculosis (all kinds), 178; typhoid, 87. These figures, however, represent only a fraction of the cases, and are in the main confined to the large municipalities. It is extremely difficult to obtain satisfactory notification in face of the conservatism of the native, his dislike of the disinfection of his home, and other troubles entailed by the discovery of infectious disease therein. Tuberculosis is notified much more freely than other diseases. Measles assumed epidemic proportions during the first half of the year, but after May gradually subsided. A small outbreak of plague occurred in May, June, and July. Small-pox became epidemic in the second half of the year. The majority of the cases were notified in Baghdad and Basrah, but the disease was much more widely spread throughout the country than indicated by the figures. The epidemic reached its summit in the first half of December, after which the figures dropped suddenly. Cholera has been notable by its absence, and there have been very few cases of typhus and relapsing fever.

The X Ray Institute, Baghdad, is the central radiographic institution of the country, and is also the depôt for supplies and repairs to all civil and military X ray installations. It is fully equipped with the latest radiographic and electrotherapeutic apparatus. A branch institute has been established at the Civil Hospital, Basrah. Arrangements have also been made to open another branch at Mosul. The work of the Vaccine Lymph Institute, Amarah, proceeded uneventfully. During the year 14,513 grammes of lymph (sufficient for 1,902,600 insertions) were manufactured and 7235 grammes issued. With this increased production it has become possible to keep in stock lymph of recent manufacture only, and lymph is now discarded as soon as it is 12 months old. The work of the laboratory of the Chemical Examiner's Department has continued at a high standard. The equipment is now complete and up to date; 376 samples were received for analysis, as compared with 313 in the previous year. The proportion of military work has decreased to about a tenth of the total. The laboratory is proving to be of considerable value to other departments, notably railway and excise. The Public Works Department is also beginning to refer to the chemical examiner for help and advice in such matters as concretes, cements, &c. Although the Rabies Institute at Baghdad is at present a military institution, it cannot be passed over without notice. Resulting from negotiations between the Director of Health Services and Government of India and the Assistant Director of Pathology, General Headquarters, Iraq, the institution commenced work in July, 1921: 159 cases have since been sent to the Institute for treatment. Of these, 137 underwent the full course. One refused treatment, and in other instances treatment was not considered necessary. The presence of the Institute in Iraq has resulted in an average monthly saving in passages alone of about Rs.3500, in so far as civilians are concerned, in view of the fact that previously all cases had to be sent to Kasauli, India.

For medical arrangements the railway system is divided into two sections, one extending from Makinah to Diwaniyah, and the other from Diwaniyah upwards, each being under a separate railway medical officer, and the whole being under the control of the chief railway medical officer at Baghdad. Railway dispensaries have been established at Makinah and nine other centres. During the early part of the period under review the treatment of railway employees was partly dependent on military hospitals. This dependence on the military has been gradually eliminated with the development of the Railway Medical Department, and during the latter part of the year, with the coöperation of the civil hospitals, attendances at or admissions to military hospitals have ceased. All sick now among railway employees, who cannot be treated at railway dispensaries, are received into civil hospitals, and practically the only patients dealt with by military hospitals are those requiring evacuation to India on medical grounds by ambulance transport. Owing to the large reduction in the imported railway personnel, the number of patients has considerably diminished, so that the pressure on civil hospitals has been much lessened, and this is noticeably so now, with the establishment of a new railway hospital at Baghdad West.

Up to a certain period the Iraq levies depended on the Civil Health Service for medical treatment, but on the reorganisation of the force a new Levy Medical Service was instituted under the control of Director of Health Services, with S.M.O. (who is also Assistant Director of Health Services), two R.A.M.C. inspecting officers, two assistant surgeons, eight sub-assistant surgeons, and two dressers on loan from military. In addition to this trained personnel, subordinate medical orderlies were supplied by levies. Instruction in medical and sanitary duties has been carried out. Now all the posts are provided with facilities for treatment to a finish, and for supervision by a British medical officer. Stations in Mosul, Arbil, Kirkuk, and Sulaimani took over the medical equipment left by the military, while small detention hospitals were instituted at Khanagin, Baghdad, Diwaniyah, Samawah, and Nasiriyah. The Civil Medical Stores supply medical equipment, and the Civil Health Service place their hospitals at the disposal of levies for the treatment of severe cases. The civil surgeon, Kirkuk, and civil surgeon, Sulaimani, officiate as levies medical officers, in addition to their other duties.

At the beginning of 1921 the Health Service transport consisted of two launches, five touring cars, 12 ambulances, and ten vanettes. Some of these were not in good order, having been running continually for two or three years. Running repairs were high, and the services of good drivers were difficult to obtain. Early in the year a reduction of four touring cars was effected, while the number of vanettes on actual duty was reduced to five, the rest being dismantled. Since then every effort has been made to utilise slow transport where possible; but it would seem that the present establishment is necessary for moderate efficiency.

HEALTH CONDITIONS IN TOGOLAND (WEST AFRICA).

A REPORT, prepared by Captain E. T. Mansfield, District Commissioner and Record Officer, on the British Mandated Sphere of Togoland for the year 1922, has been received at the Colonial Office. Amongst other interesting items it contains the following: "It is worthy of comment how eagerly the natives are seeking the aid of European medicine, and the long distances from which some of the patients travel to obtain it. . . . Native chiefs have instructions to report all cases of serious or infectious diseases without delay. This system has been proved very satisfactory by the fact that an outbreak of small-pox was immediately reported on a cocoa trade-route, and that, therefore, the possible beginning of an epidemic was controlled at its outset by the sanitary department and practically confined to one village. Medical attendance is given free to all paupers who care to apply for it, and for a nominal fee of 1s. to people of the labouring classes, whilst those who are known to be fairly well off are expected to pay higher fees. The medical officer performs a monthly tour through the districts. The most important diseases locally are venereal; the cases thereof treated during the year very easily outnumbered all others. Malaria and helminthiasis come next in importance and are very common; otherwise, except for injuries, many of which would be of a trivial nature if the natives possessed the most elementary ideas of sepsis, the local inhabitants appear to be fairly healthy on the whole. Sleeping sickness is met with, but is extremely rare, and leprosy also is not common. . . . There is no professional prostitution in the territory, the reason for this being that the morals of the people are so lax that what amounts to practically promiscuous fornication is so common that there is no room for such a class. It is quite a recognised business among a

certain section of the women, who go off to large centres to amass affluence in order to buy finery. A large number of the women from the southern section of the area frequent the brothels in Lome, which, it is understood, were in the past recognised and supervised by the German authorities, and have now been reintroduced by the French. Brothels are not recognised in British territories. No stigma appears to be attached to the profession. The whole subject of immorality and its attending diseases is of the utmost importance to the whole of West Africa, as it is one of the most potent factors limiting the increase of the population. . . . Restrictions on the importation and increase in the cost of alcohol have been the causes of inducing the inhabitants to resort to the excessive consumption of palm wine in the pine-growing areas. There are no other locally manufactured alcoholic liquors, except in the northern territories, where a quantity of corn beer is prepared. . . . The measures taken to assure the regulation and control of the importation, production, and consumption of dangerous drugs are prescribed by Rule 31 of 1921 under the Opium Ordinance of the Gold Coast Colony: 'Every application for the export to an importer of a supply of opium shall be accompanied by a certificate signed by the P.M.O. of the Gold Coast that the import of the consignment in question is approved by him, and is required for legitimate purposes. In the case of medicinal opium, morphine, heroine, and similar drugs, the certificate shall state specifically that they are required solely for medicinal or scientific purposes.' . . . Survivals of domestic slavery are still met with in the remote parts of the country, but it is impossible to furnish statistics, owing to the careful measures adopted by the slaves themselves and their masters to conceal their correct status. It must, however, be remembered that the state of slavery does not entail that character of servility which arises in the ordinary sense of the word. . . . Full liberty of conscience and unrestrained exercise of all forms of worship, which are consistent with public order and good morals, are permitted. The majority of the people are pagans and follow ancient customs. Fetishism is, therefore, the dominating religion amongst the population of Togoland. Adherents of the Christian religion, in many instances, still uphold the spirit of the Fetish influences. Polygamy is very prevalent. The individual will marry in church, but in the majority of instances insists upon having more than one wife. In these cases he is permitted to attend the church, but is barred from partaking of the Lord's Supper."

THE FLOODS OF PARIS.

WHILE the recent floods of Paris never reached the catastrophic level of January, 1910, they have caused considerable disorganisation in medical activities as in the general life of the city. In THE LANCET of Feb. 5th, 1910 (p. 390), we gave an account of the difficulties under which the hospital services and private medical practice had to be carried out, conditions which happily have not been repeated in the same degree of severity. As was the case 14 years ago, the first announcement of the effects of the inundation that has come to us through the Paris medical press was a short statement from the *Paris Médical* to the effect that their printing offices had been completely flooded. Consequently the first few issues of the *Paris Médical* for the present year will be delayed and the journal is meanwhile appearing in the form of a small supplement, printed elsewhere. We regret the misfortune which has befallen our contemporary, and trust that the damage it has sustained will be of a temporary nature only.

MEDICAL BOOKS AND JOURNALS FOR CENTRAL EUROPE.

A CORRESPONDENT has called our attention to the eager welcome which English medical books and journals receive in Hungary at the present time, where the poverty of the universities prevents the students from obtaining foreign technical works of any kind, although many of them speak and read English. France has already done something to make its literature accessible to the Hungarian people. We call attention again to the facilities for sending medical books and journals to Central Europe, afforded by the Universities' Library for Central Europe. This library works in coöperation with the Universities' Committee of the Imperial War Relief Fund and is now amalgamated with the literature department of the European Student Relief with headquarters at 16, Boulevard des Philosophes, Geneva, Switzerland, so that there is no duplication of effort. During the last year consignments of books have been sent to Austria, Czecho-Slovakia, Finland, Germany, Hungary, Poland, Roumania, and Russia, along with several sets of scientific journals including the *British Medical Journal*, *The Lancet*, *Nature*, and the *Journal of Pathology*. Free transport facilities are accorded to the Library by the Governments of Czecho-Slovakia, Finland, Germany, Poland, and Roumania, while consignments for Russia are transported free of charge by the Red Cross Society of Russia direct to Moscow, whence they are distributed by a representative of the European Student Relief. Medical books and journals may be sent to the Hon. Secretary of the Universities' Library at the London School of Economics, Houghton-street, W.C. 2, and earmarked for any particular destination.

We are also asked to state that the British Legation in Belgrade would be glad if any readers of *The Lancet*, who do not wish to keep their copies for binding and are willing to incur the postage, will send their copy, when read, to L'Association des Médecins Assistants des Hôpitaux, Hôpital Civil, Belgrade, Yugoslavia. Also that Prof. Richard Werner, director of the Samaritan House at Heidelberg (Inst. for Exper. Cancer Research, Vossstrasse 3), would gladly receive any recent books and pamphlets on the subject of cancer.

A TEST OF DEATH.

To the Editor of THE LANCET.

SIR,—Whether the popular belief that people have been accidentally buried alive is well-founded, one does not know; but the cynically disposed might accuse us of asking for it by our sanction of death certificates without a view of the body. Now that this reproach is happily to be removed, why not adopt some simple procedure to be certified as performed in every case of death, which, without harrowing the feelings of relatives, would establish scientifically the extinction of life?

The most perfect method could be determined by experts, but I find the following in the "Manuel Pratique de la Médication Hypodermique":—

R Fluorescine 1 gm.
Carbonate de Soude 1 gm.
Eau distillée q. s. pour 8 c.c.

For s. c. injection. In case of death there is no reaction. If death be only apparent, the integument turns green in a few minutes and the eyes intensely so.

Some increase in the fee would be amply repaid by the dissipation of all fear, groundless or otherwise, of one of the most horrible of possibilities.

I am, Sir, yours faithfully,
Jan. 13th, 1924. E. O'CONNOR.

*** The injection of fluorescin for this purpose is mentioned in many text-books. It is a qualitative test to determine whether circulation has ceased.—ED. L.

AVIATION AND DEFECTIVE SMELL.

AIRMEN have most of their senses and functions exhaustively examined already, but now comes Mr. A. L. M. Flamme, médecin aide-major de 1re classe[1], who thinks their sense of smell too should be investigated before they are admitted to training. There are smells which are danger signals to the pilot—e.g., burning petrol, showing risk of fire; petrol unchanged, which means a leak; burning oil, suggesting overheating of the cylinders and so engine failure; burning rubber, from failing insulation. All these connote serious risks, of which the sense of smell gives the first warning. Defective smell may imply trouble in the nerve centres, hysteria, previous injury to the head, rhinitis, or nasal obstruction, any one of which may diminish the pilot's efficiency. Defect however is not very common. Mr. Flamme examined the olfactory condition of 100 air craftsmen, and found only one who could not distinguish petrol, orange, or peppermint among the test solutions offered to him; this man failed to recognise that camphor in a 1–50,000 solution had any smell at all.

CANON MILLER.

A CORRESPONDENT asks us how the well-known General Hospital for South-East London came by its name, and the story happens to be interesting to ourselves. The original institution, which can be shown by actual records to have been in existence for 140 years, was called the Kent Dispensary, afterwards the "Royal" Kent Dispensary when it came under the patronage of Queen Victoria, the daughter of the Duke of Kent, but not until 100 years after its foundation was the dispensary turned into a hospital when certain wards were erected. This addition to the dispensary formed a memorial to Canon Miller, the rector of Greenwich, who had started a Hospital Sunday Fund at Birmingham during his incumbency there. With Dr. James Wakley, then Editor of THE LANCET, Canon Miller became the joint founder of the Metropolitan Hospital Sunday Fund, and the first meeting to organise that Fund was held in the editorial room of THE LANCET with Canon Miller in the chair (see THE LANCET Centenary Number, Oct. 6th, 1923, p. 739).

An Address

(ABRIDGED)

ON

TUBERCULOSIS WORK IN ENGLAND.*

BY A. SALUSBURY MACNALTY, M.D. OXF.,

A MEDICAL OFFICER TO THE MINISTRY OF HEALTH: SECRETARY, TUBERCULOSIS COMMITTEE OF THE MEDICAL RESEARCH COUNCIL.

[AFTER a brief sketch of the pioneer work in tuberculosis effected by voluntary measures, work which was watched by the State with ever-increasing attention, Dr. MacNalty went on :—]

PROGRESSIVE INTEREST OF THE STATE IN TUBERCULOSIS.

Scientific Investigations and Royal Commissions.

The interest of the State in tuberculosis dates from the early days of health organisation in England. After Villemin in 1865 had made his classical communication on the transmissibility of tuberculosis before the Academy of Medicine in Paris, Sir John Simon, medical officer of the Privy Council, enlisted Sir John Burdon-Sanderson's aid in carrying out experiments which confirmed those of Villemin, and announced the findings in his reports to the Privy Council in 1867 and 1868. Also, both before and after Koch's discovery of the tubercle bacillus much research work was carried out by Klein and others on tuberculosis, with the assistance of scientific grants from the Local Government Board; these researches are embodied in special reports which well repay perusal. In this connexion I would refer to the investigation into soil dampness as a cause of tuberculosis made by the late Sir George Buchanan (Ninth and Tenth reports of the Medical Officer of the Privy Council, 1866 and 1867). It will be recalled that the results obtained in this inquiry were supported by the independent work of Bowditch in America.

A further stage in the deepening concern of the State with tuberculosis was seen in the appointment of the Departmental Committee in 1888 to consider, among other matters, the best method of dealing with tuberculosis with a view to checking the progress of the disease in cattle. About this time, also, experiments were being carried out on the subject of tuberculous meat under the direction of the Veterinary Department of the Privy Council; records of these experiments are to be found in the annual report of that department for the years 1890 and 1891. Brief allusion may be made also to the Royal Commission on the question of the effect, if any, of food derived from tuberculous animals on human health. The first of these was appointed by the Government in July, 1891, of which Lord Basing was chairman. On Lord Basing's death the Commission was reconstituted in 1894 under the chairmanship of Sir George Buchanan. It examined many witnesses, and organised searching researches on definite prearranged lines. It reported in 1895, the conclusions as to the effect of the consumption of tuberculous milk on human health being specially important. Obviously, more stringent administrative measures were demanded, and in 1896 another Royal Commission considered this aspect of the question. Its findings received legislative recognition in the Dairies, Cowsheds and Milkshops Order of 1899.

In 1901, at the Tuberculosis Congress held in London in that year, Prof. Koch announced in his historical address that he felt "justified in maintaining that human tuberculosis differs in important respects from bovine tuberculosis and cannot be transmitted to cattle." He added that repetition of the experiments which had caused him to make this assertion was desirable; in his opinion, the infection of man by bovine tuberculosis was so rare that for practical purposes it might be ignored. The Government felt the issue to be of such importance that on August 21st, 1901, a Royal Commission, with the late Sir Michael Foster as chairman, was appointed to inquire and report with respect to tuberculosis: (1) Whether the disease in animal and man is one and the same; (2) whether animals and man can be reciprocally infected with it; and (3) under what conditions, if at all, the transmission of the disease from animal to man takes place, and what are the circumstances, favourable or unfavourable, to such transmission. The Commission worked for ten years, and published a valuable series of reports which indicated that Koch's statement could not be accepted in its entirety, that human tubercle bacilli can infect cattle under experimental conditions, whilst bovine tubercle bacilli are responsible for a considerable proportion of human tuberculosis, especially among children.

In 1902 the Local Government Board instructed the late Dr. H. Timbrell Bulstrode, one of their medical inspectors, to visit the public phthisis sanatoria in this country and report upon the various aspects of the sanatorium question. The report, a bulky volume of 670 pages, was published in 1908. In addition to detailed descriptions of English sanatoria, it gives a comprehensive account of the state of scientific knowledge of tuberculosis at that time, and considers many aspects of the tuberculosis problem. The report should be more widely known and more widely read than has been its fate hitherto. In 1909 Sir Arthur Newsholme, as medical officer of the Local Government Board, wrote an important memorandum on Administrative Measures in Tuberculosis, in which much of the tuberculosis organisation now in force was distinctly foreshadowed.

Establishment of the School Medical Service.

The establishment of the School Medical Service by the Board of Education in 1907 had an important bearing on the prevention and treatment of tuberculosis in the child. First, many minor ailments and conditions favouring or predisposing to tuberculosis were recognised by school examination and removed by the treatment advised, given or enjoined on the parents to be procured; secondly, when a tuberculosis service came into being, opportunities for the treatment of tuberculous children under the schemes of local authorities were available through the coördinated work of the school medical officer and the tuberculosis officer. The labours of the School Medical Service—as the annual reports of the Chief Medical Officer of the Board of Education clearly indicate—have already secured a great reduction in the incidence of tuberculosis in children of school age.

Notification.

Scotland, always in the van of progress, regarded pulmonary tuberculosis as an infectious disease within the meaning of the Public Health (Scotland) Act, 1897. In England and Wales, in a few towns prior to 1908, all cases of pulmonary tuberculosis were notifiable under local Acts of Parliament, while in an appreciable number of urban and rural districts voluntary notification of cases of pulmonary tuberculosis was invited by the sanitary authority and secured in some proportion of the total cases of this disease.

In 1907 special encouragement was given by the Local Government Board to the voluntary notification of cases of pulmonary tuberculosis; in 1908 the Board issued the Public Health (Tuberculosis) Regulations, making notification compulsory for cases of pulmonary tuberculosis, who came under the care of Poor-law medical officers, either at home or in Poor-law institutions; these regulations were followed by the Public Health (Tuberculosis in Hospitals) Regulations, 1911, providing for the compulsory notification of cases of pulmonary tuberculosis receiving treatment in public institutions; the Public Health Regulations (Tuberculosis), 1911, made the notification of all cases of pulmonary tuberculosis compulsory. Finally, in 1912, the Board's Order, extending compulsory notification to cases of all forms of tuberculosis and

* Delivered before the Tuberculosis Society on Jan. 18th, 1924.

consolidating the three previous orders as to notification, came into force. Notifications are sent by the medical practitioner to the medical officer of health of the district in which the patient is residing. Under the regulations the medical officer of health is made responsible for the action needed to trace sources of infection, or to remove conditions favourable to infection. This responsibility rests with him whatever may be the local system of organisation as to tuberculosis.

The National Insurance Act, 1911.

The resources for attacking the problem of tuberculosis were strongly reinforced by the passing of the National Insurance Act, 1911. This Act, which applied throughout Great Britain, dealt, as regards tuberculosis in insured persons, with (*a*) treatment, (*b*) erection of sanatoria, and other institutions; (*c*) research; and (*d*) education. It was open to the obvious criticism that only the insured persons in the community received specialised treatment for tuberculosis, and that the measure was not one of general public health.

The Departmental Committee on Tuberculosis.

The Government were naturally aware of this criticism and lost no time in meeting it. In 1912 the Lords Commissioners of His Majesty's Treasury appointed a Departmental Committee, under the chairmanship of Mr. (now Lord) Astor, to report at an early date upon the consideration of general policy in respect of the problem of tuberculosis in the United Kingdom. The Committee were also to consider the problem in its preventive, curative, and other aspects, and to advise the Government and local bodies as to the making or aiding of provision for the treatment of tuberculosis in sanatoria or other institutions or otherwise. The Committee issued two reports, an interim report in 1912 and a final report in 1913. In these reports the whole field of tuberculosis was surveyed, the available machinery was considered, and practical advice was given as to the organisation of schemes for the prevention and treatment of tuberculosis under the National Insurance Act.

Two important findings of this Committee were: (1) that any scheme which is to form a basis for the control of tuberculosis should be available for the whole community; and (2) that the organisation of schemes through the country can best be carried out if undertaken by local authorities.

TUBERCULOSIS SCHEMES FOR ENGLAND UNDER THE LOCAL GOVERNMENT BOARD.

In their circular of May 14th, 1912, the Local Government Board expressed their general agreement with the findings of the Departmental Committee on Tuberculosis, as set out in the interim report, and urged all county councils and county borough councils in England to formulate a scheme which should provide for the treatment of cases of tuberculosis within their area. There was a general consensus of opinion—already expressed, as we have seen, by the Departmental Committee—that complete schemes, not limited to insured persons, but available for the entire population, must be undertaken for effective control over tuberculosis. For these complete schemes funds other than those available under the National Insurance Act were required. In their circular letter of Dec. 6th, 1912, the Local Government Board stated that the Government were prepared annually to provide a sum of money equal to half the estimated cost of treating non-insured persons, including dependents of insured persons, under any scheme approved by the Local Government Board. The grant is often called "The Hobhouse Grant," as it was first announced in a letter from the Chancellor of the Exchequer to Mr. Henry Hobhouse, Chairman of the County Councils Association.

To summarise the position. The schemes for the treatment of tuberculosis, applying to the whole population, insured and uninsured, were carried out by county and county borough councils. The Local Government Board acted as a sanctioning or advisory body, and also as a subsidising body. A similar function is exercised by the Ministry of Health at the present time. The Board also gave grants to local authorities towards the establishment of institutions for the treatment of tuberculosis out of a sum of £1,500,000 which was set aside under the Finance Act, 1911, for this purpose. The scale of capital grants was: dispensaries, four-fifths of the cost, but not exceeding £240; sanatoria and hospitals, three-fifths of the cost, but not exceeding £90 a bed. The annual cost of a tuberculosis scheme was defrayed in the first instance by the local authority. There were receipts from the Insurance Committee to be taken into consideration, and half the deficit was paid by the Local Government Board. The money for this purpose was voted annually by Parliament. The remaining half of the deficit was borne by the local authority out of rates.

It is a tribute to public enterprise that in the majority of instances agreement and coördination were effected between the local authority and the Insurance Committee, but the complexity of the machinery available for this purpose undoubtedly delayed the submission of schemes for the treatment of tuberculosis. The passing of the Ministry of Health Act in 1919, which devolved the provision of sanatorium treatment upon local authorities, was generally welcomed; it put an end to the artificial distinction between the insured and the uninsured tuberculous patient.

The Tuberculosis Scheme.

The complete scheme for the prevention, detection, and treatment of tuberculosis adopted by the Local Government Board was virtually that recommended by the Departmental Committee on Tuberculosis. It was based on the establishment and equipment of two units related to the general public health and medical duties carried on by the medical officers of health working in harmony with the general practitioners. It was laid down by the Local Government Board (circular letter of Dec. 6th, 1912) that the organisation of schemes must be undertaken as part of the public health administration of the area to which they relate with the medical officer of health as the chief administrative and organising officer. The advantages of coördinating the preventive and therapeutic sides of tuberculosis under one administrative head are obvious, and are now generally recognised.

The first unit of the scheme consists of the tuberculosis dispensary or an equivalent staff. The second unit consists of the sanatoria, hospitals, &c., in which institutional treatment is given. The aims of the scheme were thus stated by the Departmental Committee:—

> The Committee are of opinion that the tuberculosis dispensary should be the common centre for the diagnosis and for the organisation of treatment of tuberculosis in each area at which the various bodies and persons connected with the campaign against tuberculosis will be brought together. The aim should be that no single case of tuberculosis should be uncared for in the community, and that whatever services the scheme provides should be available for all cases of the disease. Next to the tuberculosis dispensary should stand the second unit, consisting of a system of sanatoria, hospitals, farm colonies, open-air schools, &c. The tuberculosis dispensary should be linked up to these institutions, for which it will act as a clearing house.

In practice, therefore, a complete scheme approved by the Local Government Board would provide for: (1) the medical officer of health of a county council or county borough as chief administrative officer; (2) tuberculosis medical officers appointed by the local authorities; (3) dispensaries (including a system of health visiting); (4) sanatoria for early cases (5) hospitals for intermediate and advanced cases. In accordance with Section 16 (1) (*b*) of the National Insurance Act, insured persons suffering from tuberculosis might be placed upon domiciliary treatment—that is, they could be treated in their own homes by the panel medical practitioner.

By July 18th, 1914, appreciable progress had been made by local authorities in preparing complete

schemes; 192 clinical tuberculosis officers had been appointed in England. Dispensary premises were established for the most part by the adaptation of an ordinary dwelling-house rented by the local authority. The chief difficulty lay in the provision of residential institutional accommodation. All institutions of repute for the treatment of tuberculosis obtained the temporary approval of the Local Government Board at the outset of the campaign; but the demand for beds far exceeded the supply, and it was soon evident that local authorities either independently or in combination must provide their own residential institutions. Accommodation for early intermediate and advanced cases was sadly lacking; also, as regards provision of beds for children, treatment of surgical tuberculosis, and after-care work, little had been done by 1914. Yet much of the field had been surveyed, plans had been prepared or were in course of preparation, and already the machine of organisation was moving steadily if slowly when its progress was arrested by the outbreak of the war.

Tuberculosis Administration During the War.

The war adversely affected the national campaign against tuberculosis in various ways. Certain county medical officers of health and many tuberculosis medical officers joined the Naval or Army Medical Services. The medical officers who were entrusted with their work could do little more than "carry on" under the existing methods of organisation. War conditions rendered it difficult to keep even a minimum service in being, and still more difficult to make any progress with the development of official schemes. It was necessary to impose restrictions on building except for urgent war work, and in 1915 an embargo was laid on the construction of new sanatoria. These circumstances further enhanced the shortage of residential accommodation for tuberculosis in England, never, as has been mentioned, adequate for the pre-war population, and to add to the difficulties of the position in the closing years of the war there came an overwhelming demand for beds in sanatoria for ex-Service men.

Tuberculosis in the Ex-Service Man.

That military service would heighten the incidence of tuberculosis in the adult male population was foreseen as early as 1915. Unfortunately, owing to the military exigencies of the time, all available energy had to be concentrated on prosecuting the war, or more adequate provision would certainly have been made beforehand. Arrangements were made for sailors and soldiers suffering from tuberculosis to be discharged from the colours and treated under the general tuberculosis scheme; they were to be admitted through insurance committees to approved sanatoria or hospitals, and it was stipulated that they should be given priority over civilians on the waiting lists of these institutions. The cost was borne partly from insurance funds, and partly by the Ministry of Pensions. Subsequently the Ministry of Pensions made themselves responsible for the entire cost of treatment of the tuberculous ex-Service man. This demand for sanatoria beds was associated with appeals for additional residential accommodation for civilians (especially for women). Many local authorities took action, stimulated by a circular on the subject from the Local Government Board, and a considerable number of additional beds were provided. In April, 1918, the number of beds available in voluntary institutions and in sanatoria and hospitals owned by local authorities was 12,441. On April 1st, 1919, the number was 13,523, and on July 1st, 1919, the number was 14,014. Arrangements were also made for the systematic observation of the health of the tuberculous ex-soldier. Periodic visits to the home were made by the health visitor, and the tuberculosis officer, in addition to visiting the home of the patient when necessary, supervised the work of the health visitor and acted on her report. The home visitations were intended to secure as far as practicable that the patient's surroundings, mode of life, and so forth should be as satisfactory as possible, and that prompt arrangements should be made to provide treatment in a residential institution whenever this was considered desirable by the tuberculosis officer.

The Ministry of Health.

The establishment of the Ministry of Health in 1919 had an important influence upon the prevention and treatment of tuberculosis. The new Ministry became heir to the responsibilities and functions previously exercised by the Local Government Board and by the Insurance Commissioners; the Ministry was also placed in close accord with the medical services of the Board of Education, the Chief Medical Officer, Sir George Newman, retaining his previous appointment as Chief Medical Officer of the Board of Education. Again, in the establishment of the Ministry a great stride was taken forward in the coördination of the public health services. For the first time a special medical department of the Ministry solely concerned with tuberculosis was set up, of which Dr. F. J. H. Coutts is the head. This department through the organisation in force is in close association with a number of branches of public medicine and Poor-law administration, formerly in different water-tight departments in Whitehall and now assembled under the Ministry. Tuberculosis is a complex problem, and its study demands the aid and coördination of the various component parts of public health and medicine. Lastly, with the advent of the Ministry of Health central control was at once made more unified and comprehensive in regard to tuberculosis schemes.

THE INTER-DEPARTMENTAL COMMITTEE ON TUBERCULOSIS (SANATORIA FOR SOLDIERS).

This Committee was appointed conjointly by the Minister of Health and the Minister of Pensions in April, 1919, "to consider and report upon the immediate practical steps which should be taken for the provision of residential treatment for discharged soldiers and sailors suffering from tuberculosis, and for their reintroduction into employment, especially on the land." The Committee examined and received memoranda from tuberculosis officers, superintendents of sanatoria, representatives of insurance committees, representatives of public health authorities, persons engaged in the management of tuberculosis colonies, and representatives of discharged service men, and reported in August, 1919.[1] The total number of tuberculous ex-Service men, whether invalided out of the services on account of tuberculosis or afterwards found to be suffering from tuberculosis attributable to or aggravated by conditions of service, amounted to approximately 35,000. Of this number the Committee found that 22,000 had received or were at that time receiving residential treatment which had often been for far too short a period. There were some 4000 men then undergoing residential treatment. The Committee reported favourably upon the establishment of training colonies and of permanent village settlements for ex-Service men. The remaining recommendations dealt with the need for further accommodation for advanced cases, convalescent homes for tuberculous patients (admittedly an institution for a somewhat limited class of case), the reintroduction of tuberculous men into employment, and overseas settlement. The report recognised that the problem of the ex-Service man was equally the problem of the tuberculous civilian. The need for national economy has prevented the financial recommendations of this Committee from being carried out in their entirety. Vocational training sections have been provided at certain sanatoria at the cost of the Government for ex-Service men. The maximum number of places available at one stage was 510. The figures for England at the end of December, 1923, showed that 935 men had been or were undergoing courses of instruction at these centres, and that 71 remained to be instructed. The scheme has now been extended to Wales, Scotland, and Ireland, and ex-Service men for

[1] Report of the Inter-Departmental Committee, London: H.M. Stationery Office. 1919. (Cmd. 317.) 6*d*.

training are being admitted from these countries to the training sections. The scheme will come to an end on Dec. 31st, 1924.

It is interesting to note that the Central Fund for the Industrial Welfare of Tuberculous Persons has embarked upon an experimental scheme for the settlement of a group of men who have received training, but who otherwise would not be able to secure employment owing to their slow rate of production. These men live in their own homes in London and attend at a workshop daily. The ideal aimed at is to enable them ultimately to work at home on orders supplied to them by the Central Trading Organisation; they will then be able to live in the smaller county towns or distant suburbs under favourable conditions; some of them may ultimately develop markets of their own. The scheme may be regarded as an attempt at "graduated settlement."

GROWTH OF TUBERCULOSIS SCHEMES.

At this stage one may pause to note the growth to which tuberculosis schemes have attained in England. A tuberculosis service is being carried out in 442 dispensaries by 349 tuberculosis officers. The number, character, and accommodation of the resdential institutions approved by the Ministry (as at March 31st, 1923) are shown in this table:—

Residential Institutions.

Sanatoria and hospitals.	Number of institutions provided by—		Number of beds provided by—	
	Local authorities.	Voluntary bodies.	Local authorities.	Voluntary bodies.
1. Sanatoria (including consumption hospitals) ..	129	69	8,221	5,075
2. Isolation hospitals (including small-pox hospitals) having beds for tuberculosis	54	—	2,287	—
3. General hospitals	1	127	20	473
4. Children's institutions ..	17	44	998	2,312
	201	240	11,52	7,860
	441		19,386	

MEDICAL PROGRESS IN TUBERCULOSIS.

The tuberculosis scheme, as set out by the State, has many advantages. It is not a rigid scheme, for every local authority within reasonable limits can formulate the scheme most suited for its individual needs; prevention and treatment are linked together; the general practitioner is an integral part of the scheme. The knowledge of an expert consultant in tuberculosis is at the service of every individual suspected to be suffering from or suffering from tuberculosis in the country; in training and industrial colonies and in after-care supervision some, though perhaps not yet sufficient, attention is paid to the important fact that tuberculosis has a social as well as a medical aspect. Furthermore, the scheme is elastic; it should incorporate every advance in treatment of the disease, and such advances have been numerous in recent years. Let me briefly refer to the most important of these advances:—

(1) *Medical Research.*—Under the auspices of the Medical Research Council research work on tuberculosis is established on comprehensive lines, and is closely coördinated with the work of the Ministry of Health. There is a General Committee, a Bacteriological Committee, and a Tuberculin Committee. The latter has been engaged for the past two years in investigating the problem of tuberculin testing in cattle, an inquiry which has an important bearing not only on the purity of the milk-supply, but also bears indirectly on the incidence of bovine tuberculosis in man. The work of other committees of the Council is partly concerned with tuberculosis. Thus, the Industrial Health Statistics Committee pays attention to tuberculosis in industrial occupations; the Light Committee deals with heliotherapy in the treatment of tuberculosis.

(2) *Treatment of Surgical Tuberculosis.*—The treatment of surgical tuberculosis has been revolutionised in our own time by the work of Sir Robert Jones, Sir Henry Gauvain, Mr. G. R. Girdlestone, and others. It is not too much to say that in 20 years' time permanent crippling from tuberculosis will be regarded as a serious reflection on those concerned with the case. As yet, however, the provision for surgical tuberculosis is much too meagre.

(3) *Heliotherapy.*—The work of Rollier at Leysin, the Finsen light, the electric-arc light treatment of Reyn, of Copenhagen, now introduced by Dr. Sequeira at the London Hospital for the treatment of lupus, are all new methods of treatment which are at our disposal, and which are practised in this country.

(4) *Artificial Pneumothorax.*—For selected cases of pulmonary tuberculosis this method of treatment may arrest the disease, or at all events prolong life, and should be practised more frequently than at present. I cannot speak with such eulogy of thoracoplasty, though favourable results are reported in a minority of cases.

(5) *X Rays.*—X rays are being increasingly used in the diagnosis of cases of tuberculosis. They are essential in treatment by artificial pneumothorax, and of value in the differential diagnosis of obscure pulmonary conditions. In treatment for lupus or for tuberculous glands the results are disappointing, and the risk of carcinoma supervening in scarred tissue after prolonged treatment must be remembered.

(6) *Sera and Vaccines.*—Ever since the announcement by Koch of the preparation of tuberculin, hopes have been aroused that the discovery of an effective serum or vaccine might solve the problem of the treatment of tuberculosis. There is undoubted evidence that tuberculin in certain cases did promote arrest of the disease, but the risks undoubtedly outweigh the precarious advantages. Good results seem to have been obtained by the late Dr. Arthur Latham and by Dr. E. H. Colbeck in cases of pulmonary tuberculosis treated by Mr. H. Spahlinger's complete serum and vaccine. Unfortunately, the supply has been exhausted, and hitherto Mr. Spahlinger has not been in a position to furnish the Ministry of Health with supplies of his preparations for the purpose of a scientific clinical test. More recently still Prof. G. Dreyer has prepared "diaplyte" (*B. tuberculosis*) vaccine. This vaccine is being tested under the auspices of the Medical Research Council at several centres in Great Britain. It is too early to express an opinion as to its value in treatment, but certain of the results so far obtained are encouraging.

My purpose in alluding to medical progress in tuberculosis is to emphasise that the State is kept duly cognisant of the advances made, and is prepared to assist local authorities in putting them at the service of the community, subject, of course, to necessary financial restrictions, as soon as they are justified of medical science.

CARE COMMITTEES.

One important recommendation of the Inter-Departmental Committee on tuberculosis was that care committees should be established as an integral part of tuberculosis schemes. Unfortunately, this recommendation has not been carried out in a large number of areas. Tuberculosis is a disease bred of poverty, and in turn causing poverty. The vicious circle can be broken by appropriate medical treatment on the one hand, and by suitable sociological action on the other. The development of care work is greatly to be desired, as Dr. F. J. H. Coutts pointed out in his paper at the annual meeting of the National Association for the Prevention of Tuberculosis in July, 1923. We all recognise that the difficulties are great—e.g., dearth of skilled workers, the complex nature of the problem, and lack of local social organisations. So far as ex-Service men are concerned the British Red Cross Emergency Help Committee and the United Services Fund give valuable help; in all areas it is

desirable that their work should be coördinated with that of care committees for the tuberculous.

TRAINING COLONIES AND VILLAGE SETTLEMENTS.

This brings me to the subject of the industrial colony and village settlement, one of the most important advances in the treatment of tuberculosis, and one which the State has encouraged by financial subsidies and support. From what has been said, it will be realised that treatment of the tuberculous patient in a sanatorium under the national scheme has merely had a limited period of effective trial and in many areas only since the termination of the war. Sanatorium treatment cannot and should not be regarded as a failure. When suitable cases were selected, the method often affected partial or complete arrest of the disease. Where failure occurred it was mainly though not exclusively in the sequel of sanatorium treatment. The sanatorium patient with a recently healed lesion often went back to a pernicious environment, or was subject to the stresses of competition with healthy labour. But his is a damaged life; he cannot compete in the open labour market; his physique will not permit him to stand the strain of modern industrial life. His earning capacity declines; if the after-care committee is non-existent in his area or unable to find him a light occupation in which he can obtain a living wage he descends in the economic scale.

This sociological side of tuberculosis had engaged attention at an early stage of sanatorium treatment in this country. In some sanatoria efforts were made to prolong the period of treatment by finding suitable work for a limited number of ex-patients for a time at the institution, and by affording some degree of training in suitable occupations. Colonies represent the development of this work. It is admitted that the ideal is to treat and train the consumptive at a residential institution, and afterwards to establish him in a village settlement with his wife and family, where he can carry out his work under medical supervision and under the healthiest possible conditions. One school of thought affirms that this ideal can be attained by restricting the provision of training and occupation for consumptives to established residential institutions. It is held, then, that economic pressure will drive the consumptive worker and his family into the village settlement and industrial centre. Financial exigencies alone, however, seem to forbid the establishment of enough industrial colonies and village settlements to provide for all the consumptive workers in the country. The other school considers it desirable to make provision for industrial training and employment centres in large urban districts, such as the centre in Leeds. The patients in such centres will work on similar lines to those pursued in residential training centres; their work will be graded, they will be under the medical supervision of the tuberculosis officer, and receive financial assistance for themselves and their dependents by their labour being subsidised as in the industrial colony. In the event of a recrudescence of tuberculosis or of a slight breakdown in health they will be admitted to a local hospital for prompt treatment.

Experiments of this character are being watched by the Ministry of Health with the closest attention. They strive to offer a solution to the combined medical and sociological problems of tuberculosis. The answer may come by various roads; when it is attained local authorities should not be slow to recognise it as the crown of a tuberculosis scheme.

CONCLUSION.

In this brief sketch of tuberculosis work in England I have endeavoured to trace the steps by which isolated and voluntary measures culminated in the intervention of the State with a comprehensive and coördinated plan of organisation.

Such a scheme is of necessity costly. The total public expenditure by the Exchequer and local authorities upon tuberculosis schemes is more than 2½ millions annually.

As to the value and effect of general public health measures and special anti-tuberculosis work on the declining mortality-rate from tuberculosis we may consult the mass of valuable statistical information on the subject which is given in the supplement to the Seventy-fifth Annual Report of the Registrar-General of Births, Deaths, and Marriages in England and Wales, Part III., Registration Summary Tables (1901–10), 1919 (Cd. 8002): "The deaths assigned to tuberculous affections in the aggregate for the period 1901–10 numbered 565,161, being fewer by 50,845 than the number in the preceding decennium. Corrected for estimated increase of population the difference becomes 121,941. The statement of the number of lives saved is further increased when allowance is made for the fact that the constitution of the population in 1901–10 was more favourable to tubercle mortality than was that of the population in 1891–1900 The standardised death-rate in 1901–10 was 1646 per million living, showing a reduction of 18·6 per cent. from the corresponding rate in the preceding decennium. On this basis the reduction in the number of deaths from what might have been expected if no further fall in mortality had occurred amounts to 128,758."

During the interval of 50 years preceding 1910 mortality from tuberculosis has been nearly halved among males and more than halved among females. The period, 1860–1910, of lowered mortality from tuberculosis is associated with a certain degree of institutional segregation of the consumptive, and with education of the consumptive in measures of precaution against dissemination of the disease. The foundation-stones of a campaign against tuberculosis were being laid, and measures of this kind had a certain share at all events in effecting a reduction in incidence of the disease. Again, the same period embraces wide measures of public health and social reform. Better sanitation, better housing, higher wages, more abundant food supply, cheaper bread, better industrial conditions, and coördinated public health measures prevailed. To this realisation of the responsibilities of the community towards improving the standard of health in general, and towards the care of tuberculous persons, may fairly be ascribed the remarkable fall in the death-rate witnessed in the latter part of the nineteenth and first decade of the present century.

The standardised death-rates per million living from 1910 onwards, with the exception of the transient rise in tuberculosis mortality due to war conditions in the years 1914 to 1918, show a further progressive diminution in the mortality from tuberculosis of the respiratory system, as demonstrated in the following table:—

Year.	Males.	Females.	Persons	Year.	Males.	Females.	Persons
1910	1145	841	988	1917	1860	949	1384
1911	1206	883	1035	1918	2052	1037	1522
1912	1169	837	993	1919	1097	824	953
1913	1133	807	961	1920	966	733	843
1914	1164	839	992	1921	965	754	854
1915	1452	887	1155	1922	982	741	855
1916	1600	893	1230				

Let us glance again at the decline in respiratory tuberculosis. In 1847 the death-rate was 3189 per million, and in 1922 it was 855. In the Registrar-General's Report (1920), Dr. Stevenson, speaking of the mortality of tuberculosis, says:—

> "In the past two years this rate has fallen more rapidly than in any previous similar period of which we have record . . . . It is to this continued increase in the relative rate of fall that we must look for evidence of the effect of the anti-tuberculosis measures of recent years."

We may not see the day when tuberculosis is as rare in England as leprosy, but we can look forward to its ultimate attainment with some degree of hope. And, as Robert Louis Stevenson tells us in "Virginibus Puerisque": "To travel hopefully is a better thing than to arrive."

THE "SELF-DEFENSIVE REACTION" IN THE TREATMENT OF MALARIA.

BY IVAN I. MANOUKHIN, M.D.

(From the Institute of Experimental Medicine, Petrograd.)

THE therapeutics of infectious disease have been based, up to the present time, on the three following principles: (1) Active immunisation, introduced by Pasteur; (2) passive immunisation, first elaborated by Behring, Kitasato, Wernicke (Koch's laboratory), and Roux (Pasteur's laboratory); and (3) hæmotherapy, elaborated by Ehrlich.

The three first fundamental principles were shown by practice to be insufficient for the treatment of infectious diseases, for the following reasons: (*a*) active immunisation gives brilliant results when used chiefly for preventive purposes, as intended by Pasteur; (*b*) passive immunisation gives results only in toxic infections, its use being greatly limited by the phenomena of serum anaphylaxis; (*c*) hæmotherapy cannot be applied with certainty to most infectious diseases, especially to their bacterial forms. The necessity of finding new methods whereby the therapeutics of infectious diseases may be rescued from this unprofitable situation has therefore become urgent.

Among these methods is my own artificial stimulation of the self-defensive power of the organism, which reacts according to laws formulated by myself.[1 2] To this new principle of the therapeutics of infectious diseases I gave the name of the phenomenon upon which it is based—i.e., the "self-defensive struggle." Founded on the general law which governs the struggle of the organism against infection, this method exercises a curative action in widely different infectious diseases. Investigations carried out with the collaboration of Drs. S. Maximadji, W. Malichewsky, M. Markewitch, A. Mouratova-Koudria, Y. Sokolova, and W. Warawka have confirmed my statements concerning the value of the method; the latter curtails the evolution of lobar pneumonia and of recurrent typhus, shortens the duration of catarrhal pneumonia, and is applied with considerable success in the treatment of tuberculosis in its different localisations.[3 4 5 6 7 8 9 10] Similar success is obtained in cases of typhoid, dysentery, tetanus, &c.; these last-named infections necessitated further development of my method.[5] Consequently the "self-defensive" treatment of malaria, as I have already shown,[4 6] is only a particular instance of the application of the method.

History of the Treatment.

When medicine was enriched by the theory of the organs of internal secretion, owing to the work of Brown-Séquard and Pavlov, it became evident that the activity of the chief physiological apparatus is determined by the secretion of internal organs constituting it. Consequently, the study of the conjugated action of the different hæmopoietic organs during the self-defensive struggle of the organism against infection should be regarded in the same light.

This orientation permitted me to discover the specific ferments which produce in the blood the sequence of the phenomena comprising the self-defensive struggle of the leucocytes. The phenomena of the leucocytic reaction were definitively described by the pupils of A. Schmidt: Hoffmann,[11] Samson-Himmelstierna,[12] Heyl,[13] Groth,[14] and later on by Tchistovitch,[15] S. S. Botkine,[16 17] Rieder,[18] Löwit,[19] Wassermann,[20] and others. The hæmoleucocytic reaction consists of a succession of two processes of hypoleucocytosis, primary and secondary, separated by a process of hyperleucocytosis.[21]

Leucocytolysins and Antileucocytolysins.—My experiments showed me that the appearance of primary and secondary hypoleucocytosis in human or animal blood infected by pathogenic agents, is subordinated to the presence in the blood of ferments which condition the massive destruction of leucocytes—i.e., which constitute the phenomenon of "leucocytolysis." These ferments I have called "leucocytolysins"; they are elaborated in the spleen. The hyperleucocytosis is determined by the presence in the blood of ferments checking the destruction of white blood corpuscles, which I have called "antileucocytolysins"[1 22 23]; the latter are elaborated in the liver.[24 25 26 2]

Rôle of the Spleen.—The spleen directs all the phenomena of the self-defensive struggle of the organism. The leucocytolysins do not confine themselves to the production of hypoleucocytosis; they also stimulate the leucopoietic activity of bone-marrow as well as the antileucocytolytic activity of the liver,[2] which phenomena make hyperleucocytosis possible.

Means of Stimulation of Leucocytolytic Function of the Spleen.—When I had determined the function of ferments necessary to the hæmoleucocytolytic reaction the next problem was to find a means of artificial activation of the leucocytolytic function of spleen cells. I was able to fix the precise dose of X rays, the conditions of obtaining them, and the frequency of application, in order to get a stimulating effect only.[1 24 4 2 6] Experiments with a strictly determined dose of X rays applied to the spleen of animals gave me a profound conviction that the phenomena of stimulated self-defensive artificial reaction produced in the blood of animals an accumulation of alexine, hæmolysins, agglutinins, bacteriolysins, and opsonins.[27 2]

Treatment by Radiation of the Spleen of Animals Infected with Different Pathogenic Agents.—Under the influence of the treatment by "the self-defensive struggle" animals are cured of different infections transmitted to them. Thus it was observed in (*a*) Tuberculosis of monkeys and guinea-pigs.[2] (*b*) pneumonia of dogs, infected by the diplococcus of Fränkel, and (*c*) "Spanish" influenza of guinea-pigs infected with the *Diplobacillus morbi hispanici*, a diplococcus discovered by me in collaboration with Y. Sokolova.[29]

Leucocytolysis as Basis of Self-defensive Reaction

The constant and durable results obtained in all my experiments concerning the struggle of the organism against infection and against its toxins permitted me in 1911 to formulate the following assertion: "Biology, with all the sciences which accompany it, and medicine in particular, must henceforward modify the theory of phagocytosis by the theory of leucocytolysis and phagocytosis."[1] The immense amount of material which I have since observed now permits me to extend my generalisation as follows: "Biology must henceforward recognise that the premier rôle in the defensive struggle of the organism against infection and its toxins is that of leucocytolysis, and no longer that of phagocytosis. Phagocytosis never comes into play unless the microbes are greatly weakened and their toxins neutralised by the preceding phenomenon of leucocytolysis." The discovery of this law provided me with a link between the conception of the important rôle of the leucocytes in the leucocytic defensive reaction, and the humoral theories of immunity.

The Self-Defensive Struggle in Malaria.

I shall try to prove that the above biological law appears at the basis of the self-defensive struggle of the organism against Laveran's parasite, which constitutes a particular instance of the general self-defensive reaction. The characteristics of the leucocytic formula in malaria are as follows:—

1. *Hypoleucocytosis* (Kelsch,[30] Halla,[31] Pée,[32] Bastianelli,[33] Vincent,[34] &c.).—This process takes place chiefly at the cost of polynuclears (their number according to Bezançon and Labbé,[35] falling to 40 and even to 20 per cent.), and is observed at the period of apyrexia; its minimum (up to 3000 and even 1000) appears at the beginning of the chill which accompanies the attack—that is to say, at the moment when "the hæmatozoars, having reached their maximum development, are about to reproduce themselves by

endogenic and asexual means and present themselves in the form of 'corps en rosace'" (Billet [36]).

2. *Hyperleucocytosis* (Führmann,[37] Boeckmann,[38] Vincent,[34] &c.).—This also takes place at the expense of polynuclears (Türck,[39] Poech,[40] &c.). It begins during the chill period, immediately after the most characteristic phase of hypoleucocytosis, and reaches its maximum at the moment when "the hæmatozoars spread in the serum in the form of small amœboid bodies, in order to infect new corpuscles" (Billet [36]). According to Billet it reaches 12–20 thousand (exceptionally 25–30 thousand), continues during the whole period of fever, and ceases with the appearance of sweating, being then transformed into hypoleucocytosis, always shortly before the fall of the temperature. In that way the general characteristics of the leucocytic curve in malaria are the same as those found in all the cases of self-defence of the organism against infection; that is to say, the curve consists of alternative periods of hypo- and hyper-leucocytolysis. The only particular characteristic of the evolution of self-defence against Laveran's parasite is found in the prolongation of the periods of hypoleucocytosis at the cost of the periods of hyperleucocytosis; the latter, according to Vincent and Rieux,[41] are sustained for a few moments only in malaria.

3. *Lymphocytosis* (Bastianelli,[33] Vincent,[34] Türck,[39] Billet,[36] &c.) and *Mononucleosis* (Billet,[36] Stephen and Christophers,[42] Rogers,[43] Poech,[40] Delany,[44] &c.).—The lymphocytosis is the result of the massive diminution of the number of polynuclears; that is why, according to Vincent and Rieux,[41] the lymphocytosis particularly "characterises the interval between pyretic attacks," during which it often reaches 40, 50, and even 70 per cent. The mononucleosis is provoked not only by the diminution of polynuclears, but also by the checking action of thyroid secretion.[25] This is the reason why mononucleosis becomes a characteristic of the blood in exophthalmic goitre. With malaria, having another origin than of lymphocytosis, it is observed during the febrile periods (5–10 per cent., according to Billet [36]), as well as during the apyrexial periods which separate them (according to Billet it then reaches 25–30 per cent.).

4. *"Forms of Dissolution" of the White Corpuscles.*—These forms were first described in malaria by Petroff,[45] who commented on their high percentage from 22–33 per cent. in different forms of malaria). (This fact is of very great importance, considering that it shows us that the hæmoreaction of the human organism in its struggle with the malarial parasite is characterised by an enormous destruction of white corpuscles." Nevertheless, it must not be forgotten that the presence of the "forms of dissolution," according to the experiences of their discoverer himself (E. S. Botkine [46]), is by no means a certain indication of a disaggregation of leucocytes taking place in the blood at the moment. This question can only be solved by determination of the presence of leucocytolysins in the blood.

5. *Leucocytolysins and Antileucocytolysins.*—Since 1906 I have experimented with the leucocytolytic properties of the blood of patients suffering from different forms of malaria. These patients were under a treatment at the therapeutic clinic of the Medical Military Academy of Petrograd, at Mary's Hospital at Petrograd, and, during the war, at a Red Cross hospital under my direction, which hospital was reserved for soldiers evacuated from the front with infectious diseases. Having experimented on the blood of 47 patients, I succeeded in showing that the hypoleucocytosis in malaria really took place exclusively because of massive destruction of leucocytes in the blood. Consequently the hæmoreaction in malaria is subordinated to the general law of all infections, the law of the self-defensive reaction, based on leucocytolysis.

My observations have thus shown that the presence of leucocytolysins can be brought to light in malaria at the moment of the thermometric fall, in the period of apyrexia, during the period of hypoleucocytosis, primary and secondary; but their maximum accumulation can be established immediately before the rise of temperature, and immediately after its fall. At the moment of hyperleucocytosis in the blood, the presence of antileucocytolysins is observed; the substitution of the antileucocytolysins by the leucocytolysins always slightly precedes the beginning of the fall in temperature (see charts).

6. *Eosinophils.*—Authors (beginning as far back as Grawitz [47]) differ concerning the variations of the number of eosinophils and their significance in malaria. Of late, however, most authors agree that the quantity of eosinophils in malaria is infinitesimal, that frequently they are not to be found at all (because of the intense leucocytolysis), and that their percentage augments only when the patient is on his way to recovery; I found the same phenomena in all my patients.

7. *Irritation Cells of Türck.*—These, according to Vincent and Rieux,[41] are often to be observed in malaria in the period of apyrexia and generally in the proportion of 1 and 2 per 100 leucocytes.

8. *Myelocytes.*—In malaria a slight myelocytic reaction (Rogers,[48] &c.) is frequently remarked. According to S. S. Botkine,[49] the apparition of myelocytes is a sign of exhaustion of hæmopoietic organs, which furnish a great number of new cells in order to replace the great destruction of leucocytes continually taking place in the blood.

We have thus come to the following conception: All the particular characteristics of hæmoreaction in malaria—that is to say, hypoleucocytosis, diminution of polynuclears, lymphocytosis, "forms of dissolution," partial mononucleosis, diminution of eosinophils, and a slight myelocytic reaction—are produced by the leucocytolysis; in other words, leucocytolysis is itself the cause of the self-defensive reaction of the organism in its struggle with Laveran's parasite.

The Rôle of the Spleen in Malaria: Method of Self-defensive Treatment.

The increased production of leucocytolysins necessary to the leucocytolysis is regularly accompanied in malaria by a marked enlargement of the spleen volume. "The diminution of white corpuscles and the swelling of the spleen," as Kelsch [30] has written, "are two parallel facts in malaria." The enlargement of the spleen undoubtedly shows that the activity of this organ is insufficient for the requirements of the organism as a whole when the latter is attacked by Laveran's parasite. The radical treatment of malaria should realise an artificial activation of the function of the spleen cell, until that function fulfils the needs of the organism with regard to leucocytolysis.

The aim of my method of self-defensive treatment being the activation of the leucocytolytic rôle of the spleen, in malaria I use a dose of X rays equal to 1 h. (Holzknecht unit), as measured by the Sabouraud and Noiré radiometer; the rays are filtered through 1 mm. of aluminium, and the Holzknecht scale is used. I employ this dose for five minutes at 1 milliampere, with X rays (hardness, 8 on the Benoist radiochromometer, 15 cm. on the spintometer), with the anticathode at a distance of 25 cm. from the surface of the body.

Liver and spleen being, as we have seen, antagonistic, great care must be taken in order that during radiation of the spleen the rays should not reach the liver; radiation of the spleen should be made either from front or back, but not from the side. When the tube (8 cm. diameter for adults), whose sides are impermeable by X rays, is being placed in position, care should always be taken that the rays do not reach the left lobe of the liver. The limits of the position of the tube are at the front the left mammary line, at the back the left scapular line; the lower limit is always the lower edge of the thoracic cavity. Experience has shown me that the frequency of spleen radiations in *acute malaria* should be regulated according to the form of disease present. In quotidian fever a radiation should be given every day with interruption for five or seven days if reduction of temperature has not begun after the tenth application. In tertian and quartan fever the radiations should be made on the eve of the attack.

In *chronic malaria* spleen radiations should be applied every two, three, or five days, according to the facts of the individual case. If one series of 15 radiations is insufficient for the establishment of a complete cure the patient should be rested for a month, and treatment then recommenced, again not exceeding the number of 15 radiations. In very refractory cases a third series of radiations of the spleen should be given after another month's rest.

Methods of Manoukhin and Senn Compared.—My method of radiation of the spleen differs completely from the method widely employed since its institution by Senn. Senn introduced the use of large doses of X rays; I employ very small doses. Heavy doses have the effect of destroying the treated cells; I propose simply to stimulate the function of the spleen cells without injuring their vitality. Senn's method is concentrated upon local effect, whereas I try to obtain a general action—just as Behring, Kitasato, Wernicke, and Roux, in place of local therapeutics of diphtheria and tetanus, introduced the treatment by passive immunity of the injured organism. I have replaced local X ray treatment by stimulation of the active immunity provoked by the influence of rays on the organ which directs the defence of the whole organism against infection. By the by, I believe that Fontoynon [50] has misunderstood my method if, having identified my conception with that of Senn, "he has never seen radiotherapy alone acting in malaria."

Clinical Evolution of Malaria under the Influence of Self-defensive Treatment.

I began to apply my treatment in 1914, at Kiev, where my hospital patients included none but severe cases of malaria.

Controls.—I compared my results with those of an adjacent hospital (Hospital No. 19), where comparable cases were treated almost exclusively with quinine (after trials of arsenical preparations which were found to be less trustworthy and less stable). In a very small number of cases I was able to compare my results with those obtained by neosalvarsan treatment.

Statistics.—My figures obtained at this hospital relate to 61 cases, comprising 23 tertian, 10 quartan, 11 simple tropical malaria (*Plasmodium præcox*); 4 mixed tropical malaria (*P. præcox* + *P. vivax*); 2 pernicious malaria of a comatose and delirious form (*P. præcox*); and 11 cases where the parasite could not be identified in the peripheral circulation, and where the condition was either characterised by an irregular temperature or appeared in the form of quotidian fever. Later I was able to practise my method of treatment with the same technique at Petrograd, where I had 24 patients with chronic malaria. (I have excluded from these statistics 13 cases of acute malaria, with parasites identified in the blood, which came into my hospital by chance, and not by way of the Front. They recovered in 1–2 days after the beginning of treatment; I do not wish to base any conclusion on such favourable cases.) All the malaria patients treated by me at Kiev were definitely cured. Out of 24 patients treated in Petrograd (most of them coming from the Caucasus) I obtained a complete cure in 22 cases; 9 of these required two or three series of spleen radiations. In two cases where the spleen was voluminous and very much indurated I was obliged to stop the treatment after several trial radiations; the splenic tissue, having undergone too great a fibrous degeneration, no longer reacted to excitation, and the production of leucocytolysins was nil. After this experience I was astonished at the unexpected conclusion drawn by Tanon, Gastou, and Segal at the time of my communication in December, 1922.[50] They believed that my treatment was "especially indicated in cases where chronic alterations of liver and spleen are present." I have just shown that chronic alterations of the spleen constitute a considerable obstacle to the success of my treatment, necessitating a much longer time and, in exceptionally severe chronic cases, rendering treatment inactive. Normal function of the splenic cell is thus absolutely necessary for my treatment.

Fall of Temperature.—The influence of X rays on the spleen most frequently began to appear in the temperature only after the eighth to tenth radiation, as the cases were severe. These 8 or 10 radiations—and sometimes even 3 to 5 radiations—were sufficient to reduce the temperature to normal. In some cases 10 to 15 applications were needed, but I have never had to go beyond 20 to overcome the most recalcitrant cases of quartan and tropical fever. The method of fall of temperature in my cases of acute malaria differed widely; sometimes the fall was abrupt, sometimes the pyrexial periods diminished progressively and the temperature fell by lysis. In certain cases, before the definite fall, tertian or quartan fever was transformed into quotidian fever; the temperature then fell at once, abruptly or with several oscillations.

The four charts (Figs. 1, 2, 3, 4) show axillary temperatures of soldiers treated and cured by me at the Kiev Hospital.

FIG. 1.

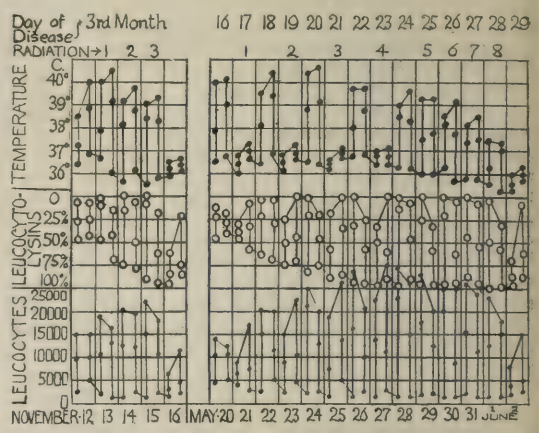

FIG. 2.

FIG. 1.—Patient, aged 22, treated in November, 1914; *P. vivax* identified; quotidian fever; the temperature fell abruptly and finally after the third application of rays.

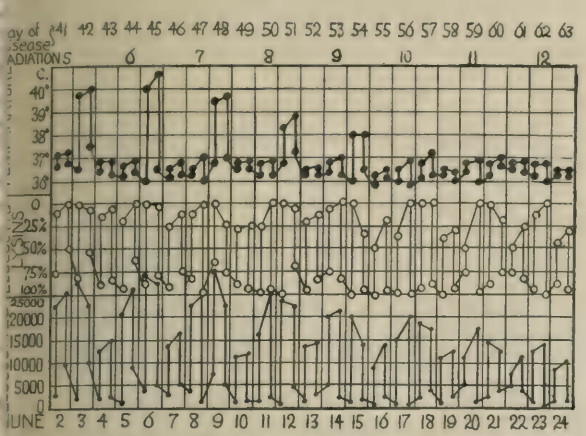
FIG. 2.—Patient, aged 25 years, treated in May, 1915; tertian fever; *P. vivax* identified; temperature fell by lysis after eight radiations; tertian form transformed into quotidian form.

The charts show that identification of the parasite does not make it possible to foresee the number of radiations of the spleen which will be necessary. Thus, six radiations were required for the treatment of a mixed form of malaria due to *P. præcox* + *P. vivax* (Fig. 4), whereas 8 and 3 radiations were needed respectively for two cases (Figs. 1 and 2) determined by *P. vivax* alone. Nevertheless, experience has shown me an incontestable sign on which prognosis can be based. When tertian or quartan fever is transformed into quotidian fever, it can be stated that the disease is giving way to treatment, and that the fall of temperature to normal is imminent. It is equally impossible to foresee by means of the temperature curve whether the latter will fall abruptly or by lysis. The rapidity of this fall to normal in acute malaria treated by radiation of the spleen depends entirely on the patient, whose physical resistance and psychical state play a preponderating part in the matter. At the Kiev Hospital the patients who required longest treatment were prisoners of war, psychically depressed, and soldiers exhausted by enormous marches and insufficient nourishment.

Disappearance of Clinical Symptoms.—The liver and spleen diminished in volume with the fall of temperature and, in acute cases, resumed their customary dimensions either at the time when the temperature has reached the normal, or else in the following eight days. In malaria accompanied by icterus the latter disappears with the fall of the temperature.

The patient's weight goes up. The disappearance of parasites in the blood is accompanied by a rapid increase of the quantity of hæmoglobin. The red corpuscles also take on their normal aspect and their number shortly reaches the usual figure. The explanation is as follows: I was able to establish the fact that

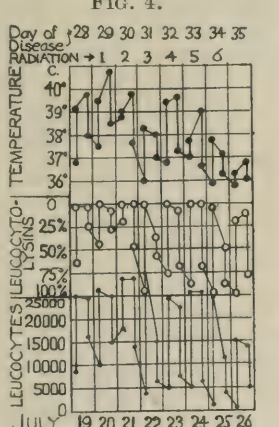
FIG. 3.



Patient, aged 24, treated in June, 1915; quartan fever; *P. quartanum* identified; the temperature fell by lysis after 12 radiations.

radiation of the spleen provokes an increase of red corpuscles and of hæmoglobin in the blood. Recent communications of Béclère [51] and Vaquez [52] confirm the observation that spleen radiation with small doses of X rays leads to an increase of red corpuscles in blood. It is of importance to remember this detail of the action of X rays upon the spleen, for in no case should treatment be stopped before the hæmatological formula has returned to normal. Thus I follow this rule: About 15 days after the last radiation, if blood examination shows that the quantity of hæmoglobin and the number of red corpuscles are not yet normal, another few supplementary radiations should be practised under the control of frequent hæmatological examinations. This eventuality does not often arise after 15 days; the blood formula of the patient cured of acute malaria is usually normal. If supplementary radiations are necessary they should be made every 5–6 days.

FIG. 4.



Patient, aged 25, treated in July, 1915; mixed tropical malaria; *P. præcox* + *P. vivax* identified; irregular intermittent fever; temperature fell definitely after sixth radiation.

Advantages of Self-defensive Treatment.

From a comparison of results obtained at Kieff by the self-defensive treatment and by quinine, in the two hospitals before alluded to (my own and No. 19) I drew the following conclusions: 1. No. 19 hospital, where quinine was used, had deaths to report, whereas my hospital had none. 2. The benign clinical evolution of malaria in the patients submitted to the spleen radiation was striking, their general condition improving after a few applications of the rays. 3. The duration of the disease was shortened on an average to nearly a third of the duration observed with quinine treatment. 4. No. 19 hospital contained some more or less pronounced quinine-resistant forms of malaria; patients who left my hospital all showed a definitive return to the normal conditions of the blood. 5. Several relapses were observed in quinine cases, even before the patients had left hospital; I was fortunate in being able to keep in my hospital all patients who had undergone my treatment for at least a month after their recovery. It was also possible to examine about 50 per cent. of my patients a year and two years after the end of their treatment; in none of the 50 per cent. could any return of malaria be found or reported. 6. Finally, in self-defensive treatment we have a powerful expedient in cases of quinine idiosyncrasy. I was able to report to the Société de Médecine et d'Hygiène Tropicales de Paris a case of this idiosyncrasy cured by self-defensive treatment.[50] Comparison of the results of my method with those obtained in the few available cases treated by neosalvarsan gave still more strikingly in favour of the former.

Regular Reproduction of the Hæmoleucocytolytic Reaction by Self-Defensive Treatment.

The constancy of positive results obtained by self-defensive treatment can only exist on condition that this treatment reproduces exactly the phenomena of the defence of the attacked organism.

A distinguished Russian clinician and therapeutist, S. P. Botkine,[53] used frequently to state that "The faculty of cutting down, of aborting the morbid state exists in the human organism itself; the problem is to track it down and render more efficacious the means which the organism uses for getting rid of the infection. It seems to me that in the study of these natural abortive forms, in the knowledge of procedures utilised by the morbid organism we shall find means of aborting disease." The laboratory and the clinic have definitely established my conviction that leucocytolysis appears to be the process utilised by the organism to free itself from any infection; I propose artificially to provoke the process by means of a new principle of treatment, by "the self-defensive struggle," which I have instituted and have here described.

REMARKS ON THE PATHOGENICITY OF COMMON INTESTINAL WORMS.

BY WILLIAM NICOLL, D.Sc., M.D. ST. AND., D.P.H. CAMB.,
MEDICAL OFFICER OF HEALTH, SOUTH SHIELDS.

NO ONE will deny that parasitic worms play a definite and far from unimportant rôle as pathogenic agents, but for some inexplicable reason they are generally regarded as the special concern of the *tropical* pathologist. The suggestion that the commoner helminths have any part in the causation of diseases occurring in this country appears to arouse in certain quarters considerable opposition, and in view of this it is not surprising that helminthology, as a branch of medical and veterinary science, has received comparatively scant attention and encouragement. It is, therefore, the more remarkable that anyone here should have attained eminence in this particular subject. As it happens, comparatively few have.

It is not particularly easy to account for this peculiar circumstance. Parasitic worms are admittedly common enough even amongst the apparently healthy, and, moreover, more or less sound teaching with regard to them finds a place in the best text-books of pathology published in this country, though it is perhaps doubtful if it occupies a proportionate amount of time in the class-room, the teaching laboratory, and the clinic. As a result one cannot avoid the conclusion that diseases due to helminths are not, as a rule, recognised. The remarkable and exceptional cases which have been recorded from time to time bear witness to this supposition.

It would be unreasonable to expect the busy general practitioner to devote the time necessary to establish in every case a diagnosis of intestinal helminthiasis. In many cases of oxyuriasis, of course, a reliable diagnosis can be based on a few well-known symptoms. In most cases of ascariasis and trichocephaliasis, however, the symptoms are either obscure or so pleomorphic that quite a variety of different diseases, not necessarily intestinal, may be simulated. In illustration of this, such cases as those reported by Jamieson and Lauder (1910) and Kahane (1907) are of interest. Moreover, the literature on the subject is so scattered that an altogether unreasonable amount of time is usually wasted in ascertaining its existence and in collating the various items. On that account it would seem that some useful purpose might be served by presenting these items in an accessible form. An equally desirable object would be attained in drawing attention to the fact that a fairly comprehensive literature on the subject does actually exist and that it deals with many varied aspects. As to the precise value of this literature doubts may justly be entertained in particular instances.

In this connexion the bibliographical work of J. C. Huber[1] served a very useful purpose. It has, however, been merged in the much more comprehensive and voluminous "Index Catalogue of Medical and Veterinary Zoology."[2] Amongst the more useful bibliographies of subsequent date are those of G. Railliet[3] and Leiper.[4]

The Conclusions of Railliet.

To my mind the most important and unprejudiced opinions which have hitherto been published on the subject are those of Railliet, who, it should be noted, is a clinician and not a helminthologist. These opinions, though not immune to criticism, are eminently reasonable and free from bias. As the volume in which they were published is rare, I take the liberty, with the author's permission, of presenting here a translation of his principal conclusions, which are as follows:—

Intestinal worms are, in general, more frequent in infants than in adults; ankylostoma, however, is rare, and bothriocephalus exceptional in infants. The frequency of the different species varies according to the country. In Paris trichocephalus is very frequent, oxyuris little less common, and ascaris rarer. The last is more widely distributed in rural districts.

In former times nervous disturbances were those most frequently noticed because they are most striking. They have been described as sympathetic or reflex, but they ought really to be regarded as toxic, infectious, or toxi-infectious. They occur almost exclusively in predisposed subjects of a neuropathic disposition. At the same time, the influence of coexisting digestive troubles must not be ignored. These multiple factors make it difficult to determine exactly the part attributable to helminths in the production of these ill-effects. Nevertheless it is certain that helminths are the occasional, if not actually determining, causes of convulsions and of various obscure troubles classed under the term "neuroses," of which the number is constantly diminishing. The reality of verminous pseudo-meningitis, in particular, is proved by lumbar puncture. This is of differential importance, as the prognosis in such cases is, of course, favourable. There also occur ocular troubles of such importance as to demand cognisance on the part of ophthalmologists.

The study of cutaneous disorders, apparently neglected by dermatologists, opens a field for much interesting research. Amongst the local disturbances the peri-anal lesions of oxyuris will certainly be found to be more frequent than would appear. The ætiology of pruritus ani is not well known. Moreover, the subject of erythema is one on which a chapter remains to be written.

Accidents of a surgical nature, due almost entirely to ascaris, are of varied interest. Intestinal perforation is theoretically possible, but no observation has so far been absolutely convincing. The occurrence of primary verminous abscesses is not proved beyond question. Except in the unusual case reported by Fröhlich (oxyuris), the cases deal in reality with peritoneal collections in direct communication with the lumen of the intestine. The occurrence of intestinal obstruction, however, is quite beyond question and is of great medical and surgical interest. Tumours, due to clumps of ascarids in the intestine, may give rise to errors of diagnosis.

Worms, generally oxyuris, are frequent in the appendix of children, but they appear to be as frequent in normal as in affected appendices. Both oxyuris and trichocephalus frequently occur in the wall o

the normal appendix, and may thus inoculate bacteria into the wall. The possibility of helminthic appendicitis is therefore real; only its frequency is in doubt. Anthelminthic treatment has been found of no avail for worms in the appendix, and, indeed, its employment may be actually dangerous in cases of acute appendicitis. Two points must be noted—namely, that the presence of worms in a case of appendicitis constitutes a possible source of aggravation, and that ascarids sometimes give rise to symptoms simulating appendicitis (pseudo-appendicitis).

Gastro-intestinal disturbances are usual in helminthic infections, and may simulate a variety of diseases such as muco-membranous enteritis, dysentery, cholera, &c. Trichocephalus enteritis, however, does not appear to present a sufficiently clear-cut picture to be classed as a definite morbid entity. Intestinal worms may cause fever. Transient febrile states are frequent enough, but the question of helminths as inoculating agents of typhoid fever remains sub judice.

The existence of helminthic anæmias is now generally admitted. Trichocephalus and ankylostoma may cause severe, even fatal, anæmia; but only bothriocephalus anæmia presents the characters of a pernicious anæmia. Intestinal worms not infrequently migrate, especially into the bile-duct and pancreatic duct; or into the respiratory passages, where they may cause fatal asphyxia.

In certain cases helminths appear to have caused sudden death, and have thus become of medico-legal interest.

In summing up, Railliet suggests that, while avoiding the exaggerated misconceptions of the past, it appears advisable to constantly bear in mind the possibility of untoward contingencies due to parasitic intestinal worms. In the case of obscure children's ailments every practitioner ought to put the question to himself, "Has the child worms, and, if so, what kind?" In any case of doubt, where no contra-indication exists, a vermifuge might with advantage be administered.

Notes Based on Personal Experience.

Little comment on the foregoing is necessary, but the following notes, based on personal experience, may not be out of place. The subject of nervous disturbances associated with worms is one on which a volume could be written. These may assume various forms, but are most commonly of a choreiform or "hysterical" type. Amongst the most classical is the well-known phenomenon of dirt-eating (*pica*), which is frequently well marked in hookworm cases. This, however, is only a special instance of the general symptom, vicarious appetite, common to infections with most intestinal worms, and not by any means confined to human cases.

The association, under certain circumstances, of parasitic intestinal worms with ocular disturbances has been observed by numerous clinicians. Here again toxic action is called into account, but in certain cases—e.g., ankylostoma—the ocular troubles, such as hæmorrhages, are similar to those not infrequently met with in cases of anæmia of non-parasitic origin.

The occurrence of cutaneous disturbances is, to my mind, not the least cogent evidence of toxic action. So far as one can judge, the phenomena are somewhat analogous to those associated with serum rashes. Quite a number of cases are on record, amongst the most interesting of which are those discussed by Ransom at a meeting of the Helminthological Society of Washington in 1922. As Railliet correctly concludes, much remains for investigation in this connexion

That intestinal worms may cause, or be associated in the causation of, enteritis there is not the slightest doubt. Even excluding the large number of cases in which worms are simply concomitants of other enteritis-producing organisms—bacterial, protozoal, &c.—there remain many in which intestinal worms are, indisputably, at least the initiating cause of the trouble. While no one would suggest that ascaris or trichocephalus is a cause of typhoid fever or cholera, yet there are many indications that worms may function as potent predisposing or accessory factors in these diseases. Guerrini's statistics (1915) in regard to cholera, for instance, undoubtedly point that way. The actuality of enteritis due to strongyloides is also beyond dispute. The fact that this worm, like ankylostoma, normally infects through the skin, and that before it reaches the intestine it passes some time in the tissues, blood-vessels, and lungs, would appear to suggest that by the time it reaches the intestine its extraneous bacterial contamination will be slight, if any. Again, there is no doubt that when it does eventually reach the intestine it frequently, within a short space of time, initiates a violent enteritis. These statements, I may add, are based on the result of personal observation and experiment.

It is well known that strongyloides and ankylostoma are not infrequently associated, and their mode of infection is more or less similar, but, in my experience, early ankylostoma infections are not characterised by marked enteritis; on the other hand, early strongyloides infections and mixed infections are frequently associated with severe diarrhœa, the stools in which are almost characteristically fœtid. It seemed to me to be frequently, though not invariably, possible to diagnose the presence of strongyloides from the character of the stool alone, such diagnosis being later confirmed, quite apart from examination of the eggs, by the appearance in fæcal cultures of the heterogeneous form.

The association of intestinal worms with atypical febrile conditions has been noted. This may be taken to be correlated to some extent with toxic action, but the relation is at best obscure, and fever does not, as a rule, play a prominent part in the symptomatology of unmixed helminthic infection. It may, however, ensue as a result of gastro-intestinal disturbance. On the other hand, anæmia of greatly varying degree is one of the most frequently quoted syndromes. The nature of this anæmia has been, and still is, a matter of some difference of opinion. This is possibly due to the fact that "helminthic anæmia" is far from being a single pathological entity. The species to which anæmia of a high degree has been attributed are the hookworms and the broad tapeworm, *Dibothriocephalus latus*. The anæmias resulting from these infections are not, however, of the same type. Hookworm anæmia, at least in early cases, appears to prevent the typical features of a secondary anæmia, though it is doubtful if this description applies in every case. On the other hand, with dibothriocephalus there is no intestinal hæmorrhage, and the resulting anæmia, according to Tallqvist, resembles a true pernicious anæmia.

The rôle of trichocephalus and certain other worms in the production of anæmia is decidedly more obscure. For the present it appears best to admit that there is an element of doubt, while drawing attention to the fact that Railliet and many independent observers have brought forward clinical and experimental data to support the view that anæmia of less or greater degree not infrequently results from, or is associated with, many parasitic intestinal worm infections. This appears to be an essentially fit and proper subject of further medical research, such as is being, or about to be, conducted in France.

The Surgical Side.

On the surgical side the available data are perhaps more clear-cut, even striking. The outstanding and most frequently observed surgical lesion is biliary obstruction due to ascaris. The frequent records of its occurrence serve to indicate that its possibility should be considered in cases of obstructive jaundice. Verminous appendicitis, however, is the subject which has given rise to greatest controversy. Railliet's views are moderate, and therefore worthy of attention. His observation that both oxyuris and trichocephalus actually pierce the wall of the appendix is

significant, though not necessarily proof conclusive. It is, moreover, obvious that ascaris may cause appendicular obstruction almost as readily as it causes biliary obstruction, but whether that gives rise to, or produces symptoms simulating, appendicitis is, of course, another matter. Most strenuous of all upholders of the theory of the verminous causation of appendicitis is Rheindorf, but his very insistence naturally engenders opposition. More recently Eastwood has apparently demonstrated the absence of any causal relation between oxyuris and appendicitis. His work, though there may be flaws in its presentation, is undoubtedly the most cogent on the negative side. He argues that because oxyuris is very frequently found in normal appendices, and does not cause a local eosinophilia, it cannot therefore be a factor in the production of appendicitis. Until, however, the entity and ætiology of appendicitis can be satisfactorily demonstrated, it seems wise to admit, and bear in mind, that intestinal worms may either, indirectly, cause appendicitis or, what is of equal clinical importance, give rise to symptoms simulating that disease (pseudo-appendicitis).

How one may absolutely distinguish the false from the real has not yet transpired, but should such a distinction be clinically feasible it would have the desirable result of obviating unnecessary surgical interference. Appendicectomy has, as we know, of late years descended from the fashionable to the commonplace. Its necessity, while unfortunately only too real, is possibly in danger of becoming exaggerated. In any case, however, whether intestinal worms cause appendicitis or not, the fact will not affect the treatment, expectant or operative, of that disease, though obviously it certainly affects the question of possible prophylaxis.

A matter with which Railliet does not deal, but which has since come into prominence, is the relationship of intestinal worms to pneumonic disease. The fact that ascaris, and possibly trichocephalus, spends part of its larval developmental life in the lungs must put an entirely different complexion upon our views with regard to the pathogenicity of these common intestinal worms. A discovery such as this is added evidence, if such were wanting, of the necessity for keeping an open mind in every department of medical research. The shibboleth and the *ignis fatuus* are equally unreliable guides.

Conclusion.

It seems to me that the whole subject is one that requires and demands much further research from various points of view. While it would be absurd to accept all the observations and opinions of the older writers, amongst whom there was a tendency to ascribe many diseases of unknown ætiology to the malevolent action of very obvious worms, it appears to be equally benighted to adopt a diametrically opposed view.

This swaying of opinion is not confined to helminthology. It affects, equally, bacteriology and other branches of preventive medicine. While, therefore, the greatest caution must be, and generally is, exercised in making any positive assertion, an even greater reserve must be adopted in giving expression to any unqualified general negation—if for no other reason than that it is usually much easier to demonstrate a positive than it is to prove an absolute negative.

As from the foregoing it may be obvious that the subject of so-called "common" intestinal worms is worthy of at least a little more attention than at present it appears to receive, I venture to think that some good purpose might be served by the compilation of an up-to-date bibliography containing the more important clinical records of recent years. Such a bibliography, which I purpose publishing shortly, if it achieves no other object, may at least save the time of others who may be interested in the matter, and who may have occasion to consult the available, but unfortunately much scattered, literature on the subject.

THE "ELECTRONIC REACTIONS" OF ABRAMS (E.R.A.).

BY F. HOWARD HUMPHRIS, M.D. BRUX., F.R.C.P. EDIN., D.M.R.E. CAMB.,
PAST PRESIDENT, AMERICAN ELECTROTHERAPEUTIC ASSOCIATION.

Dr. Albert Abrams claimed that his "electronic reactions are either the greatest miracle of the age, or else the greatest fake," and after careful investigation it would appear that this second claim is justified. A brief and concise definition of what is meant by "electronic reactions" is well-nigh impossible, but a general idea may be gained by studying the principles as set forth by Abrams. These are:—

"1. Physiologic phenomena are manifestations of electronic energy.

2. Pathologic phenomena are manifestations of perturbed electronic energy.

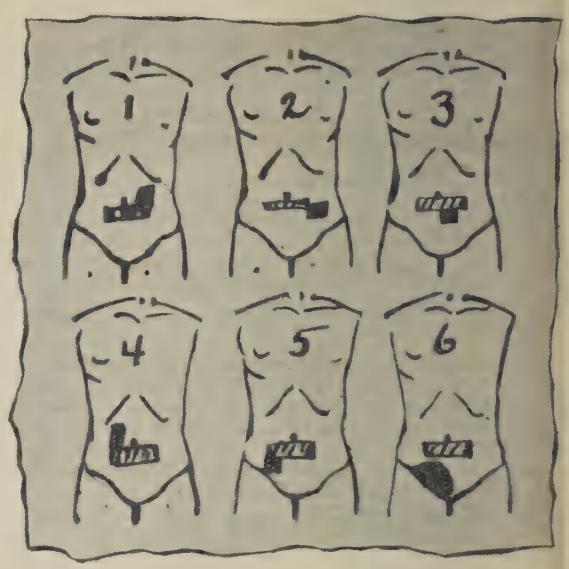
3. The energy in health and disease has an invariable and definite rate of vibration (determinable by the electronic reactions).

4. Specific drugs possess a like vibratory rate as the diseases for which they are effective. These like vibratory rates (homovibrations) of drugs owe their efficiency to their inherent radio-activity.

[So an obsolete drug like gamboge painted on the chest in incipient tuberculosis will effect a symptomatic cure within a few weeks. Gamboge possesses the same vibratory rate as tuberculosis. Our conception that drug action is dependent on cellular contact is thus demolished.]

5. All forms of energy whether derived from heat, electricity, or magnetism may be made to yield different rates of vibration and these rates corresponding to the diseases are utilised for their destruction."

FIG. 1.



This chart represents the areas of dullness Abrams claims to have found in determining the religion of individuals by means of the E.R.A. (1) Represents the areas of dullness for Catholic, (2) Methodist, (3) Seventh-Day Adventist, (4) Theosophist, (5) Protestant, (6) Jew.

These rates of vibrations are obtained or determined by means of an instrument known as the oscilloclast. It has also been called in the United States press—

"A contraption which might have been thrown together by a ten year old boy who knows a little about electricity, to mystify an eight year old boy who knows nothing about it."

Abrams says that it is an apparatus for treating diseases by definite rates of vibration on the theory that every disease has its own vibratory period and that by increasing the force of the vibrations by means of the oscilloclast you shatter the disease.

It is possible that the electronic theory is not yet

quite so clear that a quotation from its originator may help to make it more intelligible :—

"Electrons and not cells are the units of the body. Electrons are charges of electricity and the basis of the material universe, including man. Electrons have invariably uniform vibrations, and it is only in the rate of vibrations

FIG. 2.

The "oscilloclast" (patent pending) as pictured in *Physico-Clinical Medicine*, June, 1919.—(From the *Journal of the A.M.A.*)

that we can distinguish one object from another object . . . During the revolutions of electrons, thousands of billions of times per second, their vibrations (radiations) escape. Many are perceived as light, heat, electricity, and so on, but most of them are unrecognised, because they have thus far eluded all scientific instruments.

Vibrations can destroy disease. Every object has a natural period of vibration. If one approaches an object with a source of vibration of the same vibratory rate as itself, the object will be set in vibration. This forced vibration of the object may attain such a magnitude as to fracture and utterly destroy it. Caruso could take a wine glass and determine its tone (vibratory rate) by tapping it. Then by singing that tone in the glass, would shatter it. This is exactly what happens when you impose on a disease its own vibratory rate by the oscilloclast."—"Catechism of the Electronic Methods of Dr. Albert Abrams." Abrams.

Thus every illness is due to erroneous vibrations of the electrons. Up till now we have believed that the size of an electron is so minute that the most powerful microscope is useless to render it visible to the human eye, and that there is no direct means of measuring the size of it. But the discovery of Abrams, if proved, would upset our present conception of matter. The education of electrons and teaching them their proper vibratory rate, thereby curing the diseases which their faulty vibration is causing, is a claim with which no scientific discovery of any age can compete.

The three diseases which are usually diagnosed and (or) treated by the Abrams method are syphilis, malignant disease—chiefly carcinoma—and tuberculosis. But the claims of Dr. Abrams are by no means limited to the diagnosis and cure of disease. By means of another instrument which he calls the "sphygmobiometer," which has been called by a detractor "a bunch of junk," he claims to establish the parentage of a child through comparison of the vibrations of a drop of the child's blood with those of the blood of the supposed father. He has appeared in the witness box in a court of law to give evidence in support of determining the parentage of a child. It is not on record that the court accepted the test as final.

Another claim, perhaps not so sensational but equally bewildering to the man whose scientific education is limited to the more generally accepted theories, is that he can with a tuning-fork measure the vibrations of light waves emitted from colours, these being in the hundreds of millions and the maximum vibrations of tuning-forks being about 16,000. Nor does the tale of the marvellous claims or suggested claims allied to the basic discovery cease here. There is an Abrams theory which attributes sexuality to sound, and also to numbers, while by the E.R.A. it is said to be possible to determine the religion of individuals. Fig. 1 is a reproduction from Dr. Abrams's own journal (*Physico-Clinical Medicine*, September, 1922).

These areas of religious dullness are obtained and other diagnoses made by the Abrams oscilloclast. This is a box on the outside of which is a motor and a current breaker which run when the machine is connected to the ordinary electric lighting circuit. There are also two controls, the function of which is not evident. The current breaker is not electrically connected to anything at all (Fig. 2).

The diagram of the wiring (Fig. 3) is particularly interesting, for with our own knowledge of electricity it would appear to be impossible for any electric current

FIG. 3.

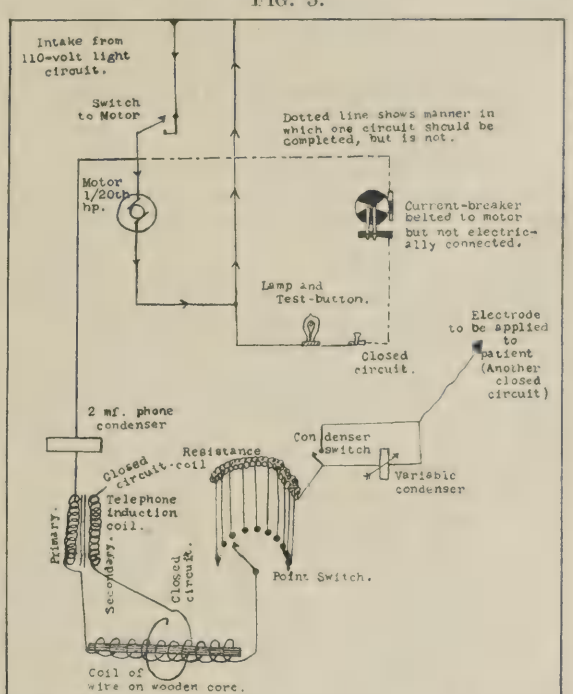


Diagram of the wiring of the oscilloclast.—(From the *Dearborn Independent*, February and March, 1923.)

in any form to pass from the intake (top left-hand corner) to the patient (right side), and this is borne out if a galvanometer be placed between the electrode and the patient, no deflection of the needle can be seen to be taking place at any time.

There is a shelf inside the box which separates the upper half from the lower. In the centre is an "induction coil" consisting of one wire wound round a wooden core and covered with paraffin and a pasteboard tube, the whole thrust through a wooden wheel around which is wound one strand of wire which is then cut off, completely closing the circuit and insulating the two wires by means of some 4 inches of wood. Had we not Dr. Abrams's assurance to the contrary, we should have to believe that this coil is worthless so far as the transmission or induction of electricity is concerned, which is the conclusion of Mr. Frank Rieber, head of the Rontgen Appliance Corporation of San Francisco. Shorn of technical wording a report of experts, of which Mr. Rieber was one, at the instigation of the *Dearborn Independent* made four important findings.

1. That no current appreciable to the most delicate galvanometer passes from the oscilloclast to the patient. Since the vibrations are carried by the electric current, it

is obvious that no vibrations pass from the oscilloclast to the patient.

2. That the construction and the wiring of the interior of the oscilloclast is such that no electrical current could pass through the machine, and that this wiring and construction show a profound ignorance on the part of the inventor of all the laws of electricity or of handling of the electric current.

3. That the only possible result of the application of the electric current to the oscilloclast is the turning over of the armature of a small motor and the rotation of a small current-breaker which is belted to the shaft of that motor, both of these having been purchased by Abrams from the common stock of an equipment store and installed on the outside top of the oscilloclast.

4. That there is more electricity in a handshake, or in the "laying on of hands" than is delivered by the oscilloclast. That is to say, that the ailing human body would receive more vibration and a greater quantity of electricity from the work of a competent masseur using one hand than it would from a whole battery of oscilloclasts.

The concluding paragraphs of the report of Mr. Frank Rieber may be quoted:—

"From an observation of the internal arrangement of the oscilloclast shown on the accompanying diagram this is not surprising. Several of the circuits have no beginning and no end. That is, they are not complete, but terminate in dead-ended wires. There is therefore no place for the electricity to go on these circuits and nothing it could possibly do if it got there. Further, the electrical system in the oscilloclast does not constitute any known means for either generating or utilising the electrical oscillation. If the circuits employed have any purpose at all, this purpose is not of the sort to be evident to anyone familiar with electrical engineering or physical laboratory practice."

Now as to the manner in which this instrument is used to obtain the electronic reactions of Abrams. There are two general methods of making diagnosis, one in which the patient is present in person and the other in which the patient is represented by a specimen of blood, saliva, or handwriting, while the reactions are obtained by percussing the abdomen of a healthy young man who serves as a proxy. He stands on metal plates duly grounded. He is connected with the apparatus by means of a piece of metal on his forehead. The lights must be dimmed so as to have a minimum of light energy interfering with the delicate processes involved. He stands erect, hands held downwards, palms outwards and forwards. He must be facing west. The diagnostician sits in front of the proxy, or human reagent, and percusses his abdomen, and different areas of dullness or different percussion notes appear or disappear in varying situations according, so says Abrams, to the emanations, or vibrations, flowing from the drop of dried blood, or saliva, or handwriting, through the apparatus to the abdomen of the proxy. It should be mentioned that in order to eliminate extraneous electronic impressions the sample of blood or other matter is wiped, so to speak, with an ordinary horseshoe magnet. Later on a horseshoe magnet is suspended over the head of the reagent. This is to help to differentiate electronic reactions. When it is realised how localised is the magnetic force of a small horseshoe magnet, the extreme sensitiveness of these reactions is dimly perceived and with such extreme sensitiveness it is only natural that error may creep in from time to time, even as in the older and more firmly established medical methods. And the diagnoses made by Dr. Abrams and published by him (*Physico-Clinical Medicine*, March, 1922) appear open to fallacies or errors of experiment.

Autograph.	Date of writing.	Remarks.
Dr. Samuel Johnson	Feb. 7th, 1775.	Reaction acquired syphilis (cerebro-spinal strain) and tuberculosis.
Edgar A. Poe ..	Dec. 30th, 1846.	Cong. syphilis (cerebro-spinal) and reaction of dipsomania.
H. W. Longfellow	May 14th, 1855.	Cong. syphilis.
Oscar Wilde ..	No date.	Cong. syphilis, male reaction. Female reaction 1 16/25. Acquired syphilis (cerebro-spinal).
Samuel Pepys ..	July 5th, 1693.	Cong. syphilis (cerebro-spinal).
Bret Harte ..	No date.	Jewish on father's side. Cong. syphilis (cerebro-spinal).

These diagnoses, it will be seen, were made by the second method from samples of handwriting of deceased persons in this particular instance.

And yet one or two more examples which may tend to shake conviction in the infallibility of E.R.A. or harden the sceptic in his scepticism. The first case is reported in the *Boston Medical and Surgical Journal* (Oct. 19th, 1922):—

"At a meeting of the Massachusetts Medical Society, Dr. Abrams having, it is said, refused to submit the method to any test which was offered him said he would confine himself to demonstrating the presence of lesions 'the existence of most of which could be proved only by post-mortem examination.' A member of the staff of the *Boston Medical and Surgical Journal*, a man in perfect health, was selected for experiment. By his diagnostic methods Abrams discovered in this healthy individual a streptococcus infection, tuberculosis of the intestinal tract, congenital syphilis, and intestinal sarcoma—otherwise the man was all right! It is understood that the volunteer inconsiderately refused to submit to a post-mortem examination."

The *Journal of the A.M.A.* (Dec. 30th, 1922) relates another case, many similar cases being cited weekly in the United States. A blood specimen was collected in the presence of three reputable physicians in a town in Oklahama and sent to a Dr. E——, medical director of a "Physico-Clinical Laboratory for the Electronic Reactions of Abrams." The report was, "Congenital diminished resistance," which is a euphemism of the cult for syphilis acquired or congenital, and appears in most reports, "cerebro-spinal and digestive strain; metastatic carcinoma, liver and right colon. Tuberculosis, genito-urinary tract. Colisepsis. Streptococcic infection in gall-bladder region." The specimen of blood, it appears, was not taken from any human being at all, but was obtained from "an unsuspecting and believed-to-be virtuous female guinea-pig. The pig was duly arranged facing west when the blood was taken." To another professor of electronic diagnosis was sent a drop of blood from a male guinea-pig, and diagnosis was made. In addition, of course, to the congenital syphilis, there was "digestive sarcoma of the cardiac end of the stomach and streptococcic infection of the left frontal sinus, of the gall bladder, and '*of the left tube.*'" For the oscilloclast to be able to find a reaction for pus tubes in the blood of a male guinea-pig stamps this instrument as unique.

One more instance of the wonders of the diagnoses which are attributed to the oscilloclast will perhaps enable us to say that the claim of Abrams that "it is the greatest miracle of the age or the biggest fake" has justification. Dr. J. J. Blue, of Saginaw, Michigan, in order to test the diagnostic ability of one of the disciples of Abrams, sent a cheque and sample with a request for diagnosis. The following is a report of the diagnosis made from the sample of blood submitted:—

"Congenital and cryptogenic syphilis; congenital gonorrhœa; carcinoma of stomach, small and large intestine, colon, pancreas, kidneys and bladder; epithelioma (not localised); sarcoma of spine; chronic malaria; diabetes. That may look like a formidable array of diseases to you, but it is not so bad from an electronic standpoint. I cannot give a prognosis without a personal examination, but if all other things are equal your chances for recovery are very good."

The cheery optimism of the professors of the electronic reactions of Abrams, in face of this formidable array of human diseases, was wasted. The specimen of blood had been taken from a perfectly respectable Plymouth Rock rooster which had been confined in a well-ventilated coop since its birth. It may be that the rooster was not facing due west, or that the light was not sufficiently subdued at the time the blood specimen was taken.

I am indebted to the *Journal of the A.M.A.* of various dates; to the report on the investigation instituted by the *Dearborn Independent* appearing in the February–March, 1923, issue of that paper; and to the *Boston Medical and Surgical Journal*, and also to several numbers of *Physico-Clinical Medicine*. I have also to thank several medical men who have shown me the oscilloclast and have given me their experiences with it, but perhaps the reader will have had enough. Comment has been avoided and facts only have been stated, as they have been ascertained by observers, both as regards construction of the instrument and the nature of the electronic reactions and the diagnoses obtained.

A TECHNIQUE FOR CYSTOSCOPY IN THE PRESENCE OF PUS AND BLOOD.

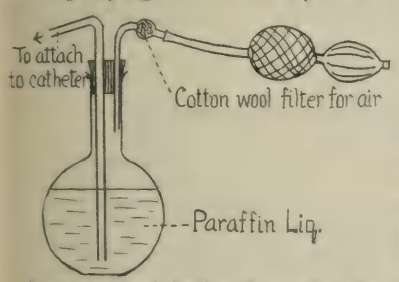
BY W. E. M. WARDILL, M.B., B.S. DURH., F.R.C.S. ENG.,

SURGICAL REGISTRAR, ROYAL VICTORIA INFIRMARY, NEWCASTLE-ON-TYNE; CURATOR OF THE MUSEUM, DURHAM UNIVERSITY COLLEGE OF MEDICINE.

IT is a matter of common experience that cystoscopy in the presence of pus or blood may be extremely difficult or even impossible, a state of affairs which may not be remedied by repeated irrigation of the bladder. The following method is suggested to overcome this irritating difficulty. I say suggested because, although the method has been used in a number of cases with success, a sufficient amount of experience has not been gained to judge of its ultimate utility or its worthiness of a place in the armamentarium of the urologist. The object of publishing this note is to afford an opportunity to all to test the method, each for himself.

The method depends for its action upon the immiscibility of oil and water, oil in this instance being used as a medium for the transmission of light. On account of the physical properties of the oil it will always remain clear and free from admixture of blood, pus, or urine.

Technique.—After the passage of a catheter the bladder is washed out in the usual manner. A sufficient amount of sterilised paraffin liq.—i.e., about 8 or 10 oz.—is injected through the catheter either by means of the apparatus shown in the accompanying sketch or by means of a Higginson syringe. It is advantageous to use warm oil at body temperature and as large a catheter as feasible. The cystoscope is dipped into sterilised paraffin and then passed into the bladder. The oiling of the cystoscope must be regarded as an important detail, since the paraffin acts in the dual capacity of a lubricant and a protective layer to the lens. The examination of the interior of the bladder is carried out in the usual manner, but it will be noted that urine passing through the ureter does not mix with the oil, and appears very much like bubbles of air. Urine and blood fall in drops, and in a leisurely fashion, to the most dependent part, where they collect together. The red colour of blood and the blue of indigo-carmine are readily recognisable, but it is conceivable that if present in sufficient quantity they might easily obscure the lowest part of the bladder wall to the inconvenience of the surgeon. There is no reason, however, why this difficulty should not be overcome by alteration of the position of the patient. At first difficulties were encountered in focusing the image, but it was later recognised that these were largely due to the insufficient filling of the bladder by the paraffin.



Apparatus for injection of paraffin into bladder.

Paraffin was chosen on account of its freedom from nocuous chemical impurities and its almost ideal transparency, but it is not supposed that the paraffin liq. B.P. is ideal. By the courtesy of Messrs. the Silvertown Lubricants Ltd., Silvertown, E.16, there has been an opportunity of testing two samples of paraffin specially prepared for the purpose. Both oils are of low specific gravity, 0·817 and 0·863 respectively. The lighter of the two is of watery consistence, the other rather more viscous; they are odourless, colourless, crystal-clear, and non-irritating to the conjunctiva. They are not combustible when exposed to air at ordinary temperatures. There is little to choose between the two oils, any balance being in favour of the heavier if used at body temperature, but either is more suitable for cystoscopy than the paraffin liq. B.P. Diathermy can be carried out with the electrode submerged in paraffin, and would seem to be a safe procedure in the absence of any quantity of air; attempts to produce ignition of the oil in an enclosed air-containing space have, so far, been unsuccessful. Diathermy through paraffin and in the presence of air in the bladder must, however, be regarded as dangerous until further experiments prove the contrary.

The practice of the method outlined above is beset with difficulties which are not at first apparent and which, with patience, are not insuperable; but it will be remembered that the method was elaborated for use in a limited class of cases where ordinary methods fail.

I am indebted to my chief, Mr. John Clay, and to Mr. Hamilton Drummond for kindly supplying cases to test the method.

Clinical and Laboratory Notes.

A CASE OF MITRAL STENOSIS.

BY DUNCAN LEYS, M.B. OXF., M.R.C.P. LOND.,

HOUSE PHYSICIAN TO PADDINGTON GREEN CHILDREN'S HOSPITAL

THE following case of mitral stenosis in a young boy is of interest in that a complete life-history of the disease was obtained. The striking features of the case were (1) the appearance of definite signs of mitral stenosis within twelve months of the onset of rheumatic infection, and (2) the leading part played by this lesion, as shown during life by the clinical symptoms and cardiac changes, in causing death five years after the first attack.

Rheumatic pains, with arthritis of wrists and ankles, first occurred at the age of 6, in November, 1918. The patient was brought for treatment to Paddington Green Children's Hospital, where he remained for one month, during which time there was no evidence of any heart lesion. Subsequently, there were no rheumatic symptoms until October, 1919, when he was readmitted to hospital with arthritis and tonsillitis: the apex beat was now half an inch outside the nipple, and an apical systolic murmur was present, but during his stay in hospital a diastolic murmur developed which, before his discharge three weeks later, had become a definite presystolic "roughening" leading up to the first sound at the apex. He remained free from symptoms, and no further evidence of re-infection occurred until January, 1923, when—after getting out of bed, where he had lain for three weeks with rheumatic pains—he became breathless and exhausted on any exertion. He was re-admitted to hospital in April, 1923. Rheumatic nodules were present; the pulse was regular, but of very small volume; a presystolic thrill was felt at the apex, and well-marked systolic and presystolic murmurs were heard; after 14 days in hospital he was able to walk about without discomfort and was discharged. The following July found him once more in hospital, with definite signs of heart failure—dyspnœa, cough, cyanosis, and palpable, tender liver. The apex beat, which was regarded as a right ventricle impulse, remained in the fifth space, half an inch outside the nipple, and percussion showed extension of the heart dullness to right of the sternum: 18 days later he was again walking without distress, and was seen shortly afterwards bathing in the Regent's Canal.

At the beginning of October, 1923, he was brought to the hospital with symptoms of heart failure. The respirations were 40 to the minute, temperature 104° F., pulse 140—regular and of very small volume: the heart's impulse extended out to the axillary border, and the presystolic murmur alone was heard, with a banging second pulmonary sound. After 14 days in bed he was able to get up, but the next day coughed up a little blood: a week later a hæmoptysis of half a pint took place; at this time there was no œdema, nor was the liver enlarged. For the next few days the temperature ranged from 100° in the morning to

103°–104° in the evening; there were signs of bronchitis, and over a small area above the liver, where he complained of pain, a pleural rub and, later, tubular breathing were heard. On the fourth and sixth days hæmoptyses of half a pint occurred, but œdema did not appear until the end of the next week, during which time occasional vomiting and slight hæmoptyses took place; the measure of urine began to decrease, but specimens remained free of albumin; the pulse was small, rapid, and regular. The following days, which preceded death, were marked by irregular pyrexia—probably due to the bronchitis and pneumonic condition—and by a gradual stasis of the systemic circulation, progressive œdema of extremities and scrotum, ascites, and great engorgement of the liver.

Post mortem, there was an excess of fluid in the pericardium, but no adhesions; the right auricle and ventricle were very much dilated and hypertrophied, occupying the whole front of the heart; the left auricle widely dilated, the left ventricle small, with healthy muscle (microscopical examination showed no evidence of myocarditis). The mitral valve showed extreme stenosis (scarcely admitting the tip of the little finger), the flaps were adherent to each other, a mass of fibrous tissue, and the chordæ tendineæ much shortened. Recent vegetations were seen on the margin of the narrowed mitral orifice, on the dilated tricuspid, and on the aortic cusps, but, apart from the mitral, there were no signs of old valvular disease. In the lungs the right middle lobe showed pneumonic consolidation; elsewhere there were numerous areas of collapse, and a few doubtful infarctions of small size, but no signs of recent or old pleurisy. There were no infarctions in the spleen or kidneys.

The cause of death in cardiac disease during childhood is usually identified with failure of the left ventricle, due to myocarditis or mechanical defect from adherent pericardium, aortic or mitral regurgitation, &c. In this case, however, the fault appeared to lie in the inability of the rest of the heart to supply the left ventricle with enough blood to maintain the circulation; this was due to a degree of stenosis in the mitral valve which would have been remarkable even in an adult heart, and was evidenced clinically by the persistently small, rapid pulse, and by the gross embarrassment of the pulmonary circulation (the boy coughed up more than half a pint of blood on three separate occasions within one week, at a time when signs of stasis in the systemic circulation were lacking).

My thanks are due to Dr. G. A. Sutherland, whose case it was, for the opportunity of recording it.

TWO UNUSUAL CASES OF INTESTINAL OBSTRUCTION.

BY CECIL P. G. WAKELEY, F.R.C.S. ENG.,
ASSISTANT SURGEON AND TEACHER OF CLINICAL SURGERY, KING'S COLLEGE HOSPITAL.

AXIAL rotation, or torsion of the pedicle, of an ovarian cyst occurs in about 2 per cent. of cases which come to operation, and this phenomenon takes place more commonly with cystic than with solid tumours. Axial rotation is met with most frequently during pregnancy and in the puerperium, but rarely gives rise to intestinal obstruction.

CASE 1.—Patient, aged 72, was admitted to King's College Hospital, June 21st, 1923, with signs of intestinal obstruction. The patient stated that two days before admission to hospital she was seized with acute pain in the abdomen and vomited several times. On admission to hospital her temperature was 98·4° F., pulse 72, and respirations 24. The abdomen was very distended, except in the flanks, and visible peristalsis was evident. A hard painful tumour could be palpated in the right iliac fossa. The obstruction was thought to be due to the tumour pressing on the lower part of the ileum, as the signs all pointed to an obstruction in the small intestine.

Operation.—Laparotomy was performed through a right paramedial incision. The small intestine was very distended. The obstruction was found to be due to a twisted ovarian cyst which was almost black in colour, adherent to the medial side of the cæcum and completely occluding the ileo-cæcal valve. The cyst, which was the size of a large orange, was carefully dissected off the cæcum and removed, together with the right Fallopian tube, which was also very congested. As soon as the obstruction to the ileo-cæcal valve was removed, the gaseous intestinal contents moved into the cæcum and ascending colon.

The wound healed well, and the patient left hospital ten days after the operation. The cyst on microscopical examination proved to be teratoma.

CASE 2.—Patient, aged 73, was admitted to King's College Hospital, Nov. 20th, 1923, with the following history. Three days earlier she was seized with acute pain in the lower part of the abdomen, which was followed by vomiting on two occasions. Previously she had enjoyed good health. On admission the temperature was 97·6° F., pulse 100, and respirations 28. The abdomen was distended; there was no rigidity, but there was some tenderness in the right iliac fossa. A bilateral swelling was found in the hypogastrium bigger on the left side than on the right. The swellings were distinct and well defined. There was no free fluid in the abdomen. Per vaginam the swelling on the left side was found to be fixed in the pelvis.

Operation.—Laparotomy was performed through a paramedial incision; two ovarian cysts were found. That arising from the left ovary was a pseudo-mucinous cyst, the pedicle of which was twisted through two and a half turns: it was found to be impacted in the pelvis. With difficulty the cyst was elevated from the pelvis and removed. The cyst of the right ovary was a dermoid; it had undergone axial rotation and was very congested and adherent to the medial aspect of the cæcum, causing obstruction to the ileo-cæcal valve. It was removed with the right Fallopian tube. The abdomen was closed without drainage. The dermoid cyst on section contained pus.

The patient made excellent progress for the first week, but then died suddenly from pulmonary embolism.

It will be noticed that in both the cases recorded the patients were over 70 years of age, and in each case the intestinal obstruction was caused through adhesions between a twisted teratomatous ovarian cyst and the cæcum.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

GRADING OF THE POPULATION FROM THE POINT OF VIEW OF PHYSICAL FITNESS.

A SPECIAL meeting of this Society was held on Jan. 21st at 1, Wimpole-street, W., Sir WILLIAM HALE-WHITE, the President, in the chair.

Air-Commodore DAVID MUNRO, in opening a discussion on this subject, said it was complex and far-reaching, being mixed up with fundamental, social, economic, and political problems, some of which had been subjected to close study by the best brains in the medical profession. The late war had shown the physical state of our manhood to be far below what the average man thought it to be. The war-time pronouncement of a well-known politician, who declared "We are a C 3 people," was untrue for certain classes of the population, but for other classes it was pretty well agreed to be true. Thus, while miners and agricultural labourers were found to have a high index of physical fitness, as judged by Keith's standard, those engaged in sedentary industrial occupations were found to have a low index. The report issued by the Ministry of National Service upon the physical examination of men of military age by National Service Medical Boards was the most comprehensive survey that had yet been attempted on the health and physique of a large portion of the population. Records of some 2½ million examinations carried out on men between the ages of 18 to 45 were analysed. To quote the words of the report:—

> As the result of this analysis the conclusions come to were that of every nine men of military age in Great Britain on the average *three* were perfectly fit and healthy; *two* were upon a definitely infirm plane of health and strength whether from some disability or from some failure in development; *three* were incapable of undergoing more than a very moderate degree of physical exertion and could almost—in view of their age—with justice be described as physical wrecks, and the remaining man was a chronic invalid with a precarious hold on life.

As matters had existed in the past only the stress of a great national struggle could have brought into existence, and caused to function, the machinery for

conducting such a number of medical examinations, and for analysing their results, and it might well be wondered what practical possibility there was in peace-time of obtaining records to show the state of physical fitness of any large section of the population and, if obtained, to what practical use they could be put. He would endeavour to give a sketch of (*a*) the value of such records, if obtained; (*b*) the amount of information necessary to be recorded: (*c*) the possible method of obtaining and recording it.

Value of Records and Amount Required.

The picture presented would indicate the directions in which efforts should be made to improve health generally, and as such the figures would be of great value to the Ministry of Health.

To the physical culture teachers these figures would be of value in giving them a picture of the different classes. Figures of this kind, giving information of the *fit* classes of the population, would undoubtedly be useful in the future in the consideration of eugenic problems, for one could not forecast what influence Malthusian and neo-Malthusian doctrines might have on future policies. Information of value to industrial psychologists would be obtained. Physical fitness was a quality not capable of precise measurement. There were, it was true, certain qualities capable of exact measurement, such as height, weight, and girth of chest. Sir Arthur Keith's standard, as he (the speaker) understood it, was based on such measurements—in fact, on height measurements. But while physical qualities lent themselves to exact measurement physical disabilities unfortunately did not. To refer again to words in the report already quoted:—

> To give an exact percentage value to every known disability would present insuperable difficulties in practice. The health of individuals and of each of their component structures and organs shades off gradually, and often almost insensibly, into disease, which in its turn exhibits varying degrees of intensity which are not sharply defined from each other, and react differently on different individuals. The medical interpretation of objective clinical phenomena does not, and cannot, led itself to expression in figures.

The borderland of disease was still largely unexplored. What, then, was it necessary to do in the way of getting data about physical fitness? He believed that certain of the tests in use in the Royal Air Force, for assessment of the physical fitness of air pilots, gave results capable of numerical expression, and yielding extensive information as to the state of health of the individual tested. According to the periodic results of these tests, supplemented by a record of observed physical disabilities, he felt that individuals *might* be classified from a health point of view. The tests he would describe gave no results indicating in the subjects any special aptitude for special employments, and therefore, from the point of view of the industrial psychologist, they would be valuable in picking out the man who was physically and mentally fit for arduous work, but not the man likely to become a skilled manipulator. For these accessory tests—such as reaction-time tests—would need be employed. He would prefer to use the words "physical and mental endurance" rather than "physical fitness"—meaning that state of health which made a man able to perform an act of physical exertion not once or for a short time but repeatedly over a long period of time without undue physical or nervous stress This was a state of health which required personal care and preparation with a view to that end. Even then, every man had his breaking-point, and the fit man was the man whose breaking-point takes longest to supervene. These particular tests were originated after examination of men who had manifested such endurance—viz., star-turn pilots. The tests which he would suggest were (1) the "endurance" or mercury U-tube test, and (2) the response of pulse to exercise, or exercise-tolerance test.

The Endurance Test.

This test was performed as follows. With the nose clipped, the subject was asked to empty the lungs completely, inhale fully, blow the mercury in this tube to 40 mm., and maintain it there without breathing for as long as possible, the pulse being counted in periods of five seconds during the performance of the test. The average time of holding up the mercury in a large number of cases tested was between 50 and 60 seconds. The pulse-rate should remain steady or rise gradually according to the time the breath was held. A marked rise was unsatisfactory, and a still more unsatisfactory sign of cardio-motor instability was a marked rise during the second or third period of five seconds, followed by a dying away to normal or below normal. For the detailed physiological explanation of the phenomena of this test he would refer them to its inventor, Group-Captain Martin Flack. The factors involved were, as he understood them, (1) the state of oxygenation of the patient's blood; (2) the state of his respiratory efficiency; (3) the tone of his blood-vessels. Whatever was the actual physiological machinery functioning in this test, empirically it had proved of great value to the R.A.F. as an indication of a man's capability for physical endurance. So far it had only been used for testing flying personnel, but he anticipated its general use in recruiting centres for all personnel at no very distant date. He also anticipated that a U-tube manometer would in the future be as much a part of the equipment of a general practitioner as is a stethoscope.

Response of Pulse to Exercise Test.

The pulse-rate was taken with the subject sitting down and the total number of beats in 60 seconds recorded. If the pulse was unsteady it was counted in periods of five seconds until the minimum constant rate was obtained. The subject was then directed to stand up, and the number of beats recorded in the first five seconds multiplied by 12 was recorded as the rate per minute for the standing-up pulse. With the subject still standing the examiner then recorded the lowest steady rate to which the pulse fell. Regulated exercise was then carried out by the subject placing one foot on a chair and standing alternately on the floor and on the chair five times in 15 seconds, the speed being regulated by the examiner raising and lowering the subject's wrist in every three seconds. At the end of the 15 seconds the pulse was counted in periods of five seconds—the time which it required to fall to its steady rate being recorded in addition to the rate per minute in the first five seconds after exercise. A typical numerical record of this test in a fit man would be (*a*) sitting 72, standing 84–72, after exercise 96; (*b*) time of return to normal standing rate, 20 seconds. This test was made five times up and down only on the chair because at the time several hundred men were being examined each day. A pulse which rose rapidly on standing and took some time—e.g., 1–2 minutes—to return to its lowest steady rate indicated probably poor splanchnic vaso-motor control—in such cases the pulse maintained its quicker rate during standing. If the time of return to normal after exercise exceeds 30 seconds it was suggestive of cardiovascular insufficiency or of nervous instability. Further, this test tended to differentiate between true and false tachycardias and to throw light on various disordered actions of the heart, of which one heard so much during the war. Possibly, also, it would assist in assessing the seriousness or otherwise of valvular lesions as expressed in terms of "bruits." To sum up—these two tests were simple in application; their results could be expressed numerically and used for health classification purposes; they could also be easily codified for statistical purposes; apart from gross disabilities and special qualifications such as vision, they gave a good indication of general neuro-muscular and constitutional tone at the time of examination. The standards of fitness in the R.A.F. were set by the examination of individuals who had successfully withstood considerable physical and nervous strain in contra-distinction to those who had broken down; the psychological element in the endurance test was, he thought, of real value as a measure of the mental

"make up" (the report of the Shell Shock Committee brought out very clearly the previous lack of attention to mental standards in the course of medical examinations); the tests would be valuable as a comparative test of fitness employed periodically, and he would suggest their use to safeguard the public in those occupations in which the element of public safety is involved—e.g., motor drivers, tram drivers, locomotive engine drivers, railway signalmen, factory machine operators, mercantile marine navigators, civilian air pilots; lastly, where employed up to date on a small scale they have given consistent results. The chief disadvantage of the tests was that temporary toxæmias upset them—mild influenza or even a heavy cold was sufficient to cause remarkable deterioration in results—hence the value of successive records. Also, of course, they gave no information about specific disabilities.

Possible Methods of Obtaining and Recording Data.

In the Services the obtaining of information was easy. If medical information was asked for, the statistics compiled from the forms rendered constituted the basis of future medical policy—though no one who filled up the forms ever believed it. If the filling up of forms was resented in the Services, in civil life it was hardly even tolerated; it would be quite impracticable to attempt to conduct any examinations annually on every man, woman, and child of the population—not only because of the difficulty in setting up the agency but also from the point of view of expense. Whatever agency were employed the coöperation of the Medical Research Council would be essential. However it might be done, he felt that some time or other some system of health classification of the population would be established.

The Government Commission.

Sir ARTHUR KEITH dated his own interest in the question of the physical fitness of the population from the appointment, in 1903 or 1904, of a Government Commission to inquire into it. The Anthropological Society had at that time suggested machinery for such an inquiry. Later, during the war, he became a member of the Committee appointed to advise the Ministry of National Service concerning the grading of recruits. With regard to the percentage of the really fit in any normal population, he did not use the data quite as had been stated. An infinite number of factors had to be considered, but it was found that of a thousand men from a part of the country with a good physical standard, 700 could be placed in grade 1, 200 in grade 2, and the remainder left over; in other parts of the country the figures were very different. The standard they had suggested had been formulated for the guidance of medical officers. At present it was no longer a matter of compulsory service, and recruits could be chosen by more exacting standards. Formerly the standard was purely that of physical appearance, weight, &c.; but these factors might fail. He considered that Group Captain Flack's work marked a great advance in methods of examination upon anything hitherto done in any country. We were seeing an extension of the movement perhaps introduced by Sir James Mackenzie—namely, the consideration of the manner in which an organ worked, the physiological method of classifying men.

Sir DUNCAN RHIND, speaking from the layman's point of view, recalled his experiences in gathering the statistics upon which the report of the Ministry of National Service was based. It was sometimes said that the National Service examinations carried out during the last year of the war were not indicative of the true state of the national health, but the fact remained that year by year there was a very large number of men called up and found unfit for any form of service. The percentage of the unfit, extending to the youths of 18, was much greater than it should have been. It would be very difficult to introduce tests on which estimates of man power could be based, but if it were possible, such tests as had been described were what was required.

The Examination of Recruits.

Dr. WILLIAM FITZGERALD said that he could perhaps speak with some little force on the question under discussion, for during the war he had been engaged solely in the examination of recruits at Liverpool. Under the Ministry of National Service alone his medical board had dealt with some 30,000 recruits, and he had previously served on the much-maligned War Office boards; even the latter, when left alone, could only find some 30 per cent. of recruits fit for general service. To a certain extent they were dealing with a residual population under the Ministry of National Service; the boys of 18 were particularly disappointing, in a great measure because they were suffering from conditions of the feet, tonsils, ears, nose, &c., which if treated earlier in life would have been remediable. The tests described by Air-Commodore Munro were most valuable; they could not replace sound clinical examination, but formed a useful adjunct. He failed to see how such medical examinations could be brought into being in this country, and referred to an instance in one of our Colonies showing how organised labour would object to them. Practically nothing had been done to remedy the state of affairs disclosed by the report of the Ministry of National Service. He had visited the slums of Liverpool on Saturdays and Sundays during the war, and had learned what they meant from the point of view of national health.

Group-Captain MARTIN FLACK explained that the tests referred to were designed solely as adjuncts to general physical examination. They were perhaps empirical, being set on subjects who had endured stress, but they seemed to show the importance of the efficiency of the controlling centres of respiration and circulation. A man who lacked good respiratory efficiency, and whose blood was not well arterialised, would quickly show signs of discomfort when breathing into a bag, giving up in under two minutes, whilst a healthier man might go on for five minutes or more. The unfit were hypersensitive to lack of oxygen. Marked respiratory inefficiency tended to be associated with laxity of the trunk muscles and pooling in the venous reservoirs, rendering the subject unable to respond to effort as the fit man was able to do.

The Tests of Efficiency.

Sir THOMAS LEWIS said that he had been out of touch with the questions under discussion since 1919, and had been particularly interested to hear about the tests of efficiency. He agreed that if they were used to test the fitness of large numbers of people, those chosen for the purpose would soon object. Examination was, however, possible in the case of men who claimed pensions. Exercise tests could not replace or be replaced by clinical examination. Men with valvular heart trouble were frequently found to tolerate exercise well; again, others who showed no signs of such trouble had poor tolerance of exercise. The tests must approximate to the forms of exercise they were intended to represent; many persons who could pass the chair test would fail if exercise were pressed further. The chair test was originally put out with some emphasis on the resulting pulse-rate, and there had arisen a tendency on the part of officers of medical boards to rely almost wholly on the reaction of the rate of the heart. It became almost a rule of thumb method, and was then misleading, since many men who showed a normal heart reaction soon displayed respiratory distress. Again, exhaustion might soon develop, the subject becoming unsteady on his feet, &c. The only really crucial test was the thing itself—to put men into the front line and see how they stood it. The individual test, again, might suit one man much better than another; a man should be put to his own work. He suggested a probational period for recruits, which, if not necessary now, might be useful in event of another problem like that of 1914. He wished to know if the mercury test had been employed mainly on young men or on men in the 'forties, who could not be expected to give the same reactions to the test.

Sir ARTHUR KEITH interpolated a few words to the effect that he had supported the idea of a probational period of a month or two months for recruits during the war.

Dr. F. W. COLLINGWOOD asked whether it would not be possible to include some test of character when examining recruits. In medical examinations for the Navy years before he had found men who passed all the tests and later showed an inability to submit to reasonable discipline.

Dr. G. H. HUNT wished to know the relative importance attached by Air-Commodore Munro to the mercury and exercise-tolerance tests. He had himself had experience with students, and had found the mercury test open to misinterpretation. He had also found the vital capacity test extremely fallacious; a very poor reaction had been given by a Rugby international player.

Colonel SYLVESTER BRADLEY said he had come to the conclusion that the exercise test was of value not as showing the amount of exercise the individual could perform, but as indicative of the latter's nervous stability. He pointed out that the period spent by the recruit at a depôt was a probationary period. Recruiting statistics were of interest as showing the alteration of incidence of various conditions such as varicose veins, which were apparently decreasing, and conditions apparently on the increase, such as flat-foot and middle-ear disease.

The PRESIDENT, speaking of his experience on the Appeal Board during the war, and as officer in charge of a hospital, remarked on the light-hearted way in which many recruiting officers treated nervous instability, particularly epilepsy, and on the harm and waste of public money this occasioned.

Reply.

Air-Commodore MUNRO, replying, said that the discussion had not developed as he had intended; he had approached it with a civil rather than a military mind. He had hoped for enlightenment as to the machinery by which examination of the population might be undertaken. He agreed that the point of the tests must be—does the man do the job? The tests he had instanced were used for flying, where the man could not be put to the work before examination. In answer to Sir Thomas Lewis's question, the tests were performed chiefly on young men, but also on every R.A.F. officer once a year, and before he was sent overseas. No marked deterioration with increasing age had been observed, but the examinations had not been carried out for a sufficient number of years for an answer to be given with confidence.

In answer to Dr. Hunt, he would point out that in any case the tests only provided bits of evidence, and could not be relied upon to the exclusion of general examination.

EDINBURGH MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this Society was held on Jan. 16th, Sir DAVID WALLACE, the President, being in the chair.

Dr. J. S. FRASER gave a communication on

Septic Otitic Thrombosis of the Cranial Blood Sinuses and Jugular Bulb,

being an analysis of 28 consecutive cases operated on between 1907 and 1923 inclusive. He said that septic sinus thrombosis was relatively more common in acute than in chronic cases of middle-ear disease. As regards sex- and age-incidence, males were more numerous than females, and 19 of the 28 cases occurred in the first two decades. A history of aural discharge commencing after measles or scarlet fever was obtained in seven cases. Only one of the cases was operated on in private practice. Dr. Fraser regarded rigors as the most important symptom from the point of view of differential diagnosis. A rigor might occur in the initial stages of brain abscess or meningitis, but recurring rigors were only found in septic venous thrombosis. The hectic temperature was typical; that of meningitis being continuous, whilst in cases of brain abscess after the initial rigor it was usually subnormal. In all cases of middle-ear suppuration associated with evening pyrexia he held that the sinus should be exposed and examined. In contrast with cases of brain abscess and meningitis, the patient usually was mentally bright and felt well. Vomiting and giddiness were present in about half the chronic cases, but in these there were complications, such as labyrinthitis, meningitis, or brain abscess. Mastoid tenderness was by no means constant. Otoscopy was usually rendered difficult by discharges and cholesteatoma. A dry tongue, showing brownish fur in the centre, was frequently noticed. Blood cultures had not proved of great diagnostic service. Dr. Fraser went on to speak of the findings at operation in the seven acute cases. Pus in the antrum and cells was present in all. Four cases showed bacteriologically a pure growth; two of streptococcus, one of diphtheroid bacillus, and one of an organism closely resembling *B. influenzæ*. In the remaining three the infection was mixed. An extradural peri-sinus abscess was present in only three. A peri-sinus abscess alone may cause evening pyrexia. In deciding whether to open the sinus, the condition of the wall is important. If this shows reddish purple, so-called "healthy" granulations, draining of the abscess may suffice; otherwise the sinus must be opened and the clot turned out. In only one case was there intracranial complication—purulent meningitis. Metastatic abscesses occurred in three of the seven cases, five recovered, and two died. Only one had an uninterrupted recovery. Both of the fatal cases developed empyema. In the 21 chronic cases cholesteatoma with or without pus was present in 15. Of 15 investigated bacteriologically seven showed pure cultures, eight mixed infection. Peri-sinus abscess was present in 14. Complications were more frequent in these cases. Eight cases had labyrinthitis, four had purulent meningitis on admission, five developed it later; four cases had brain abscess. In several cases more than one complication was present. Only four showed metastatic abscesses. Of the 11 uncomplicated cases nine recovered and two died. Of the ten complicated cases four recovered and six died. Only four of the successful cases showed uninterrupted recovery. In the eight fatal cases septic thrombosis beyond the point of operation was found. In these cases septic infarcts in the lung with empyema were present. In only one case was there septic infarction with empyema in which the blood sinuses seemed healthy. In one case death was caused by meningitis alone, and in two there was, in addition, abscess of the temporal lobe. The paper was followed by a lantern demonstration.

In the subsequent discussion the PRESIDENT, Dr. LOGAN TURNER, Dr. D. J. GUTHRIE, Dr. G. E. MARTIN, Prof. EDWIN BRAMWELL, and Dr. W. T. GARDINER took part.

Dr. CHALMERS WATSON gave a communication on

Alimentary Sepsis from the Practitioner's Point of View.

He referred to the work of Metchnikoff, J. G. Adami, Arbuthnot Lane, and others, spoke of the rôle of alimentary sepsis in present-day surgery, and discussed the possibility of the ætiological importance of intestinal subinfection, as suggested by Adami and others, in many common diseases. He regretted the nomenclature used in many diseases, stigmatising as mere labels many of the terms used. So-called anatomical diagnoses were often very misleading. He dwelt on the importance of two ætiological factors in disease—heredity and strain or stress. In the term strain he included the different forms of medical sepsis, as revealed clinically by (*a*) oral sepsis, (*b*) the condition of the urine, and (*c*) the state of the bowels, as determined by simple clinical methods of examination. With these three points in

view he had had examined 11 patients with various complaints, occupying the beds on one side of his ward in the infirmary. In all cases dental sepsis was present, none of the patients being healthily supplied in quantity or quality of teeth. Bacteriuria was present in all the cases, and the examination of the second of two colon wash-outs, which should normally be clear and fairly free from micro-organisms, showed in all cases turbidity and marked infection. He made reference to the intestinal flora in health and disease, and pointed out some of the fallacies of the usual teaching in this matter, concluding with some remarks on treatment.

Exhibition of Cases and Specimens.

MR. J. W. DOWDEN and Dr. MORRISON showed a case of fracture of the second, third, and fourth phalanges and division of the extensor tendons of the hand after operation and treatment by early active movement. After seven weeks there was full extension of the first and second fingers, fair extension of the third and fourth, and full strong flexion of all four fingers.

Dr. W. A. ALEXANDER showed three specimens illustrating unusual causes of intestinal obstruction.

Reviews and Notices of Books.

ESSENTIALS OF ORAL SURGERY.

By V. P. BLAIR, A.M., M.D., F.A.C.S., and R. H. IVY, M.D., D.D.S., F.A.C.S. London: Henry Kimpton. 1923. Pp. 526. 32*s*.

THIS book has been written primarily for the dental student. The major operations receive brief mention, but the lesser surgical procedures which come within the scope of the dentist, as apart from the oral surgeon, are fully described. The recognition of surgical conditions receives full attention, for the dentist should be competent to recognise them even though he does not undertake their treatment. Much of the material is taken from the well-known text-book by Dr. Blair on the Surgery and Diseases of the Mouth and Jaws, but there is a good deal of fresh matter on fractures of the jaws, root resection, operations for cysts, and anæsthesia. One of the best features of the book is the account of fractures of the jaw, which embodies some novel methods of treatment. The authors advocate wiring as the routine treatment for most fractures of the mandible. By this they do not mean fixation by a wire passed through the body of the jaw, but fixation by wire ligatures twisted round the necks of the teeth and drawn tight. In this way the displacement is reduced and a perfect occlusion maintained. The mouth is of necessity kept closed, but apparently this does not involve any marked degree of discomfort to the patient, though the diet must be of a liquid nature. The method is not likely to supplant the metal cap splint, which has the great advantage of immobilising the fragments and allowing the mouth to be freely used, but it has one striking merit. The materials used to fix the fracture are simple, and in the possession of every practitioner. Brass binding wire, such as can be procured from any ironmonger, artery forceps, short scissors, and towel clips represent all that is needed, whereas any other form of apparatus requires, to be effective, the equipment and resources of the dentist. The surgeon who attempted to treat a fracture of the jaw without calling in the aid of a dentist would be unwise, but under conditions in which dental aid was not available this method should prove useful, and might well find a place in text-books of surgery. There is a good account of root resection, and though the authors are cautious as to the final results of this once popular operation, they allow it a modest sphere of utility. On p. 200 we are told that foot-and-mouth disease is caused by the bacillus of Siegel, a statement which is at least premature. There are few references to other authorities, and this omission might well be remedied in future editions.

The authors have produced a useful book, which ranks among the best of its kind, and should prove equally serviceable to dentist and surgeon.

CLINICAL MEMORANDA FOR GENERAL PRACTITIONERS. Second edition. By ALEX. THEODORE BRAND, M.D., C.M., V.D., and JOHN ROBERT KEITH, M.D., C.M., Medical Officers, Driffield Cottage Hospital. London: Baillière, Tindall and Cox. 1923. Pp. 375. 7*s*. 6*d*.

THIS is a carefully compiled record of clinical experience. Certain aspects of disease which get too little recognition in practice are emphasised. These include the importance of arterial spasm in such complaints as migraine and functional paralysis, and hyperæsthesia of the skin as a physical sign in organic disease. The possibility of counter-irritation of the vagus nerve in the many diseases in which it is or may be concerned—Graves's disease, pertussis, and spasmodic asthma—is an attractive subject. Muscular overstrain as a common cause of so-called rheumatism, Bier's methods of passive hyperæmia, and the value of yeast in septic conditions are also dealt with at unusual length. There is a useful contribution on the much neglected subject of incompatibility of drugs, and a larger one on the use of individual drugs which should be of considerable interest.

Certain rules here set out we cannot altogether recommend to the junior commencing practice, to whom the preface is partly addressed; in appendicitis, for instance, Abram's sign, in which the tenderness over McBurney's point is found to disappear when the skin over the seventh dorsal vertebra is frozen with ethyl chloride, will hardly prove of value; and to lay down that "if at the end of 48 hours the symptoms have not improved operation is indicated," is surely rather understating the case in favour of appendix abscess. Of the collection of aphorisms with which the book ends, it may be said that since most rules in medicine admit of 50 per cent. exception, they must be received with some caution. Nevertheless, this type of book is only too rare. If there were more coöperation between medical men in general practice, whose splendid opportunities for observation could thus be extended over ten times their present field, we might look forward to many similar useful contributions to the symptomatology and therapeutics of disease.

PRACTICAL ANÆSTHETICS.

Third edition. By H. EDMUND G. BOYLE, M.R.C.S., L.R.C.P. Lond.; and C. LANGTON HEWER, M.B., B.S. Lond. Oxford Medical Publications. London: Henry Frowde and Hodder and Stoughton. 1923. With illustrations. Pp. 187. 6*s*. 6*d*.

THIS book is much altered in the present edition. The most striking feature of the authors' tendencies in practice is their addiction to complicated methods and apparatus in preference to simple measures. It is very likely true that the best possible results are only to be obtained in certain cases through the use of these elaborations in the hands of experts, but we greatly doubt the wisdom of recommending them as first choice in a book intended for students and practitioners who are not specialists in anæsthetics. Take, for example, this recommendation from page 163: "Endo-tracheal anæsthesia . . . should always be employed in cases of strangulated hernia, intussusception, &c., where intestinal obstruction has occurred." We doubt whether most authorities would support this advice even if the anæsthetic is in expert hands. It can be of little service to the practitioner who often has to give anæsthetics in cases of this description, and who is very unlikely to possess, still less to be able to use, an endo-tracheal apparatus. A new chapter by Dr. E. J. McKesson gives clearly this authority's views on pulse-rate and blood pressure during anæsthesia, and their significance as regards shock, and the prospect of recovery therefrom. The frequent readings that he advises would have, no

doubt, great educational value when carried out in the hospital operating-theatre by students learning anæsthetics. With regard to pulmonary after-effects, the authors state it to have been shown that "most cases of post-operative bronchitis are embolic in origin." As the true origin of these post-anæsthetic complications is such an interesting and controversial question, the reference here would have been welcome. The authors are warm supporters of ethanesal, but, nevertheless, they should have given a place to Dr. H. H. Dale's criticism of the work, both of Cotton and Mackenzie Wallis, if the book went to press after Dale's paper was published.

The book is excellently produced, is easy to read, and has much of interest to the specialist in anæsthetics.

EMERGENCY OPERATIONS FOR GENERAL PRACTITIONERS.

By H. C. ORRIN, O.B.E., F.R.C.S. Edin., Surgeon, Ministry of Pensions Orthopædic Hospital, Newcastle-on-Tyne; late Civil Surgeon to the Third London General Hospital. London: Baillière, Tindall and Cox. 1923. Pp. 1065. 15*s*.

THE motives of the author in writing this book as set forth in the preface are much to be commended, but the execution of his plan leaves something to be desired. Any practitioner may find himself in such circumstances that an emergency operation, performed by himself, offers the only chance of life for his patient. Then he needs every help that can be given him and the most elementary facts of technique should be easily available. The experienced surgeon is apt to forget that what is so familiar to him as to appear unnecessary for mention may be of great importance to the unaccustomed operator. Instructions as how to find the cæcum in appendicitis operations, or where to look for the perforated gastric ulcer, or how to detect the viability of strangulated intestine have been omitted in this work, and the oversight is regrettable. The subject of intra-abdominal traumatic hæmorrhage is not treated, so that splenectomy is not described; under strangulated hernia the operator is instructed under certain conditions to resect and do an end-to-end anastomosis, but no account of this operation appears. Some recommendations are against the best teaching, for example, the use of nails or "other fixation medium" in compound fractures. On page 11 there is a serious printer's error, where the injection of 3½ oz. of 5 per cent. novocaine is said to be safe.

The inexperienced surgeon is not likely to get the help he wants from this book.

DISEASES OF THE SKIN AND THE ERUPTIVE FEVERS.

Fourth edition. By JAY FRANK SCHAMBERG, A.B., M.D., Professor of Dermatology and Syphilis, University of Pennsylvania. London and Philadelphia: W. B. Saunders Company. Pp. 626. 25*s*.

Dr. Schamberg's book is by some considered to be one of the best of the smaller text-books of dermatology, and is exceptional in that it contains a detailed account of the eruptive fevers and the cutaneous complications of vaccination. This edition has been revised thoroughly, and the section on the treatment of syphilis entirely rewritten. The actual subject-matter is, on the whole, clearly written, and the sections dealing with differential diagnosis, in which the main points are often tabulated, are usually adequate. The directions for treatment form one of the best features of the book, and several useful formulæ are given. On the other hand, as a corollary of the irrational classification adopted, the sections on ætiology are for the most part unsatisfactory and often far from being up to date. Much confusion still seems to exist, even in the minds of expert dermatologists, concerning the so-called seborrhœic eruptions. In this book we find seborrhœic eczema, acne, sycosis, furunculosis, and carbuncle dealt with in the section on inflammations, although they are not considered together but are separated by other conditions with an entirely different ætiology; we find the seborrhœic form of alopecia described in the section on atrophies, and we find seborrhœa among anomalies of secretions of glands. The author still describes pityriasis simplex as "seborrhœa sicca," which is a contradiction in terms, and he does not even mention the so-called "bottle-bacillus." Seborrhœa and the seborrhœic eruptions are easily understood if considered in an intelligent manner according to their ætiology, and the confusion that has arisen concerning them is unnecessary and is now inexcusable. In the description of alopecia areata, the statement is made that "Sabouraud regards his microbacillus as the probable cause of alopecia areata." As a matter of fact, he abandoned this view years ago, and made a formal statement to that effect at the International Congress of Dermatology in London in 1913. No reference is made to his recent writings on this disease.

The author classifies epitheliomata of the skin into superficial, deep, and papillary varieties, but on what basis this classification is made is not clear. By the "superficial" type he appears to mean basal-celled growths, by the "deep" type tquamous-celled carcinoma; the "papillary" epishelioma "may develop from the superficial or deep variety or from an ordinary wart." No clear differentiation is made between basal-celled and squamous-celled growths as regards their histological characteristics, their prognosis, and their treatment, and the histological description is inadequate. The very superficial, multiple form of basal-celled epithelioma is not described, nor is Bowen's precancerous dermatosis mentioned; there is, however, an illustration labelled "keratosis senilis, a precarious (*sic*) condition of the skin." Satisfactory classification of diseases of the skin is impossible until we know the actual cause of every one, but our knowledge is sufficient to warrant the adoption of a more rational arrangement than is found in this book, though it is right to say that many other text-books are open to similar criticism. Under the heading of "exsudationes-inflammations" Dr. Schamberg classes together a large number of diseases, many of which have nothing in common as regards their ætiology and pathology; moreover, some can hardly be regarded even as primarily inflammatory. What possible reason, for example, can be given for including in the same section eczema, lichen planus, lichen scrofulosorum, acne, psoriasis, gangrene, the various types of ringworm, scabies and eruptions caused by other animal parasites? How can tinea versicolor or ordinary scalp ringworm be considered as inflammatory? It is inconsistent to put lentigo and chloasma in the group of "hypertrophies" and vitiligo in that of "atrophies"; and to include leptothrix, piedra, and plica polonica in the latter group is surely ludicrous. Lastly, we find lupus erythematosus, syphilis, tuberculosis, leprosy, sporotrichosis, and actinomycosis classed as new growths. Such a slipshod method of arrangement detracts materially from the value of a systematic work.

The best part of the book is that dealing with the acute eruptive fevers; this occupies nearly a quarter of the whole volume, and the eruptions and symptoms of the various diseases are described in great detail. To small-pox alone 45 pages are given, and the illustrative photographs are really excellent, as, indeed, they are throughout. But it seems to us that the author would be better advised either to enlarge the volume, so as to bring the level of the purely dermatological part up to that of the section on the exanthemata, or to publish the latter separately.

JOURNALS.

BRAIN. Vol. XLVI., Part II.—On Hepato-lenticular Degeneration, by Geoffrey Hadfield. Description of a case illustrating conclusively the existence of transition types between Wilson's disease and pseudo-sclerosis. Besides lesions of the putamen and the liver, there were focal lesions in the cerebral cortex,

characterised by prolific vascular new formation.—Rhythmical Convergence Spasm of the Eyes in a Case of Tumour of the Pineal Gland, by J. R. De Monchy. Besides the rhythmical spasm, there were found Argyll Robertson's sign, lymphocytosis of the cerebro-spinal fluid, and dystrophia adiposo-genitalis.—The Influence of the Cerebrum and Cerebellum on Extensor Rigidity, by W. P. Warner and J. M. D. Olmsted. Using cats for their experiment, the authors endeavoured to discover the exact location of the pathway from the cerebrum inhibiting tonic extensor activity. From the frontal lobe the tract passes through the mesial part of the internal capsule and below the level of the anterior corpora quadrigemina; in the greater part it then crosses to the other side of the brain stem to enter the cerebellum by way of the middle cerebellar peduncle.—The Sensory Activities of the Skin for Touch and Temperature, by David Waterston. Different thicknesses of skin were removed by blister, and it was found that when a distinct film of epithelium was left touch could be felt, but when more is removed, so that the surface is raw, no tactile sensation can be elicited. The author infers that the epithelium of the skin is the receptor organ for the sensation of touch. As a result of his investigations he finds that at single examinations hot and cold spots show a punctate arrangement, that on repeated examination the number of spots is greatly increased but that many of those formerly found no longer respond, that when a mild erythema is produced the sensation of heat can be obtained from practically all points of the affected surface. The punctate distribution of sensitive spots found at a single examination is explained by the view that in the skin there is a constant coming and going of activity in the different parts. To this he applies the term "fluctuation."—The "Law of Fluctuation" or of Alternating Periods of Activity and Rest in Living Tissues, by P. T. Herring. The assumption of this law appears to be a necessity in the case of all tissues that are subject to the law of "all or nothing." Graduation of activity in an organ made up of units subject to the law of "all or nothing," is due to a varying number of units being brought into action. The "law of fluctuation" demands an alteration of the units engaged. Examples are given of fluctuation in nerve, muscle, and glands.—Hysterical Pain, by R. G. Gordon and H. H. Carleton. In a closely reasoned paper the authors seek to show that hysterical pain is due to disintegration on the cortical level, and that the object of treatment must be to restore integration.

ANNALS OF MEDICAL HISTORY. Vol. V., No. 3. (New York: Paul B. Hoeber. $2.50.)—The first paper in this interesting number deals with a subject known to few—namely, anatomical fugitive sheets. These were single sheets of an engraved anatomical subject, sometimes with superimposed flaps, showing different layers of tissue, and Dr. Leroy Crummer has collected a vast amount of information thereon, having been fortunate enough to obtain some of these rare publications for himself.—Dr. Walter Mendelson writes upon Maimonides, his paper being inspired by the discovery by Dr. Solomon Schecter in a synagogue at Cairo of autograph letters of Maimonides and his son. Maimonides practised for a time in Cairo and Dr. Crummer gives a translation of a letter from him to a friend describing his strenuous daily routine.—Dr. M. Charlton continues his account of Medicine in Lower Canada under the French regime 1608–1759 and for some years later. This instalment contains an account of the St. Paul's Bay disease which seems to have been a virulent form of syphilis, and of another epidemic called the Molbay disease, apparently something of the same kind.—Other papers are one on the Life and Work of William Hewson, by Dr. G. H. Bailey; on the Earlier Methods in the Treatment of Syphilis, by the Editor, Dr. F. R. Packard; on Primitive Medicine in the Philippines, by Dr. A. Villegas; and on Hydrophobia Four Centuries Ago, by Dr. W. R. Riddell.

The Conduct of Medical Practice.

A Series of Articles by Experts dealing with the Difficulties Encountered in Professional Life and How to Meet Them.

IV.—TRANSFER OF PRACTICES: POINTS FOR THE PURCHASER.

BY COLIN M. OLIVER
AND
OSWALD A. HEMPSON.

Is there no physician there?—Jeremiah viii. 22.

IT can safely be stated that with comparatively few exceptions, every medical man has at some time in his professional career to consider the purchase of a medical practice, or a share in a medical practice. This is a matter of the utmost importance, and an initial mistake may have disastrous results to an unwary purchaser. The whole of the average medical man's professional education, from the time when he first commences his studies, is devoted to professional subjects. He receives no training or information in what may be called the business side of his profession, and as a consequence it is usually found that when he wishes to commence practice, he has very little idea how to set about acquiring a practice, what price he should pay, and generally what steps he should take to ensure that he is adequately protected from the pitfalls which await him, and which could be guarded against by the exercise of proper care and foresight.

In these notes it is proposed to deal with a few of the points which experience suggests may be of some assistance to members of the profession in approaching so vital a matter.

Types and Particulars of Practice.

The first point for decision is the type of practice to be acquired. Whether it is situated in the country or in a large town, and whether the patients are mainly drawn from the well-to-do or the poorer classes of the population, and whether there is to be particular scope for surgery or any particular branch of medicine, all raise different points for consideration.

Having decided upon the type of practice, the medical man's next step is to obtain particulars of such practices as are for sale of the type required. This is done by watching the advertisement columns of the medical press, or by application to medical transfer agents for particulars of any practices they may have upon their books. The particulars to be supplied from either source to enable the prospective purchaser in the first instance to satisfy himself that the practice offered for sale warrants further inquiry are shortly as follows: The annual gross receipts from the practice for the immediately preceding three years, the average number of confinements and fees receivable therefor, the scale of fees charged to private patients, information showing how long the practice has been established, number of panel patients, what appointments are held, and whether these are transferable. Full particulars should be obtained as to the residence available for the purchaser, and as to any separate surgery used in connexion with the practice, and it should also be stated whether the vendor has been in the habit of doing his own dispensing. Finally the price asked must be stated.

With this information before him the prospective purchaser will be in a position to judge whether or not the practice is likely to satisfy his requirements. If he considers that it will, he should arrange an appointment to interview the vendor. At this interview he will, of course, in the first place have regard to the neighbourhood, and make general inquiries as to the number of medical men already practising in opposition in the district, the probability or otherwise of extending the practice, the expense of running it, and whether it affords adequate opportunities for

the practice of any branch of medicine or surgery to which the applicant has any special leaning.

The residence and surgery accommodation offered should also receive special thought. The importance of this matter frequently receives insufficient consideration. The house comprises a very material item in the goodwill of a practice, and it is therefore of great importance that, if possible, the residence and surgery should be purchased, or failing this that a sufficiently long lease should be secured, to afford adequate protection to the purchaser. There have been cases where a purchaser has acquired a practice without sufficient security of tenure of the house, with the result that very shortly after the completion of the purchase he has received notice to quit. At the best in these cases he is put to the expense of finding other accommodation which may be quite unsuitable; at the worst he may be quite unable to find any accommodation, in which event he can say good-bye to the practice. Or a rival practitioner may acquire the house, and in so doing he will undoubtedly also take over some of the patients with the house.

Purchase Price.

If these preliminary inquiries prove to be satisfactory, the next, and all-important question of the purchase price has to be examined. The purchase price of a medical practice is invariably based upon a number of years' purchase of the average gross receipts. It is usual to work out the average gross receipts for this purpose from the three years immediately preceding the date of purchase. It is difficult to lay down any hard-and-fast rule as to the number of years' purchase which should be paid, as this must of necessity vary with the individual circumstances. A fair price to pay for a practice with an adequate introduction is one and one half years' purchase, but when purchasing a practice on the death of the incumbent, one year's purchase is as a rule the maximum amount which should be paid for an immediate succession. The value of a practice on a death vacancy, however, rapidly declines, and if more than a month has elapsed since the death of the prior incumbent, the price should be less than one year's purchase.

Partnership.

If the practice offered is a share in a partnership, two years' purchase is the usual price, but this again varies according to the class and character of the practice.

It is sometimes arranged that the purchaser of a share in a practice shall for a preliminary period of from three to 12 months be employed as an assistant in order that he may obtain a thorough knowledge of the practice. In this event the purchaser enters into an agreement with the vendor to serve him as assistant for the period arranged, and the agreement contains an option on the part of the purchaser to purchase a share in the practice on agreed terms, on giving notice before a specified date. It is felt by some that this is not a good method of being introduced, as the patients may for some time afterwards regard the purchaser as only an assistant, and there is a natural preference by patients to be attended by a principal.

Another and perhaps more frequent method is for the purchaser to enter into preliminary articles of partnership with the vendor for a period of from one to five years, and in this event the articles of partnership contain all the usual provisions, and, in addition, a right for the purchaser to buy the whole of the vendor's interest in the practice within an agreed period, or upon the prior death of the vendor. This is a useful method where an elderly practitioner is desirous of gradually retiring from his practice, and from the point of view of the purchaser has the advantage of giving him a prolonged and gradual introduction to the patients, but, not unnaturally, the purchase price under such circumstances would be higher than it would be in the case of an ordinary out-and-out purchase.

It is not proposed to deal at length in these notes with points which may arise on entering into an ordinary partnership, but it is well to mention one point of great importance, which is sometimes not regarded with sufficient care by a prospective partner, and that is the question of compatibility.

With the exception of marriage, there is no relationship which binds human beings together so closely as a partnership. It therefore behoves a would-be partner to study the character of the person or persons with whom he proposes to enter into such close contractual relationship, having regard to the fact that the success or otherwise of the practice will depend on how well the partners work together for the mutual good of the partnership. If there is any friction or disagreement between partners, or if there is any lack of confidence or goodwill between them, a position arises which makes it impossible for the practice to be worked to the best advantage, and may ultimately end in litigation or arbitration proceedings involving heavy expense.

Investigation by an Accountant.

Sometimes it is agreed that the purchase price shall include the vendor's stock of drugs, drug bottles, surgery fittings and effects, and sometimes these are taken over at a valuation. This point should be made clear in arriving at the purchase price. The purchaser should agree the purchase price with the vendor, subject to proper investigation of the vendor's books and practice records, in order that the vendor's representations as to the receipts of the practice may be verified. This investigation should be undertaken by an accountant, who should preferably be one who is used to the peculiarities of medical practices. A vendor who declines to afford facilities for investigation of his books should be regarded with suspicion. A purchaser who neglects to make the usual and reasonable investigation will find difficulty in obtaining relief from the courts if he discovers after completion of the purchase that the practice is not so good as he expected, when a little vigilance on his part would have been sufficient to disclose the true state of affairs. There is a maxim of law which every purchaser should keep well before him, and that maxim is "Caveat emptor."

It is inadvisable to have anything to do with a vendor who claims that he keeps no books, or that they do not show the full receipts "because of income-tax." In such cases, if the purchase is proceeded with, the purchase price should only be based upon such figures as can be proved.

Appointments and Panel Practice.

Difficulties may arise with regard to appointments held by a vendor. If the income from such appointments is included in the average gross receipts of the practice for the purpose of arriving at the purchase money, the purchaser should insist that, in the event of any such appointment not being obtained by him within a period of, say, six months from the date of the purchase, so much of the purchase money as is attributable to the remuneration from any appointment not obtained by the purchaser shall be refunded to him. The vendor in such cases will in turn insist that the purchaser should do his utmost to obtain all the appointments.

At the present time, when the future amount of the capitation fee payable under the National Health Acts is uncertain, a purchaser should require that in the event of the capitation fee being reduced within one year of the date of purchase, the purchase money should be calculated upon such reduced fee, and the difference should be refunded to him. Care should be taken by the purchaser in agreeing the purchase price that an allowance is made in respect of any reduction in the per capita fee under the National Insurance Acts, where the period covered by the average gross receipts of the practice for the purpose of arriving at the price includes such fees at a higher rate than that current at the time of purchase.

Adequate Introduction.

A purchaser should insist upon the vendor giving him an adequate introduction to the patients of the practice. What is an adequate introduction varies according to the different types of practice. It will, for instance, be longer in a scattered country district than in a closely populated industrial district. The introduction to a high-class practice has to be carried out very gradually and with the greatest tact. The purchaser should bear in mind in discussing this point that the introduction is really the only tangible part of the goodwill which he is purchasing. A clause should be inserted in the assignment of the practice to the effect that in the event of the agreed period of introduction being curtailed by the death or permanent incapacity of the vendor, there shall be a reduction of the amount of the purchase money, proportionate to the time by which the period of introduction is curtailed. In purchasing a practice on the death of an incumbent much may be done by way of introduction by the relatives of the deceased, and this should be stipulated for.

Great care should be exercised that any circular letter which is sent out is so worded as to give no offence to other practitioners in the neighbourhood. Such circular should not contain anything which savours of an advertisement or puff, and must only be sent to persons whose names appear upon the books of the practice as having been patients within the last three years immediately preceding the transfer of the practice.

If an adequate introduction is not agreed to by the vendor some reduction should be made in the purchase price by way of compensation. During the period of introduction it is usual for the expenses and profits of the practice to be shared equally between the vendor and the purchaser. An alternative is for the purchaser to bear all the expenses and receive all the profits, and to pay the vendor a fee at the rate usually paid to a locum tenens in the district. The purchase money should be paid as to part on the commencement, and as to the balance on the conclusion of the period of introduction.

Restraining Clauses.

In order to safeguard the practice to the purchaser he must insist upon the vendor entering into an adequate covenant restraining him from practising in any capacity within a given radius from the centre of the practice—usually taken from the practice house. The extent of the radius varies according to circumstances, but it should not be made wider than is reasonably necessary for the protection of the purchaser. It is useful to agree that any question, dispute, or difference shall be settled by arbitration. This method of settling disputes avoids the possibly harmful publicity which an action would entail.

It is usual for the stamp duty upon the assignment of a medical practice to be shared equally by the vendor and purchaser. In the absence of an express stipulation to this effect, however, it would fall upon the purchaser. He should, therefore, arrange with his vendor that this expense should be shared. Care should be taken that the assignment is properly stamped. If it is not so stamped, any party to it will have to pay the stamp duty and a penalty before the document can be used in any court of justice.

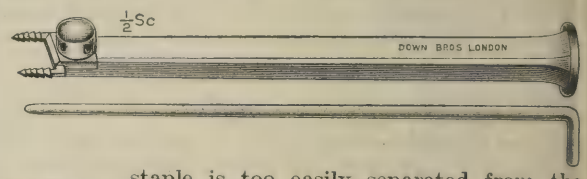
A Warning.

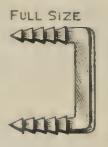
In conclusion, a few words of warning may usefully be added. A purchaser should not sign any definite offer to purchase until he has received his accountant's report. If he signs an offer it should be made subject to investigation and satisfactory report by accountants, and subject to approval of the necessary documents by his solicitors. A purchaser should not commence work in the practice until all his investigations are satisfactorily completed, and the necessary assignment of the practice is signed and completed. A purchaser should insist on the employment of a solicitor to approve the documents in connexion with the purchase on his behalf. It is astonishing how often medical men—who in their own profession would have nothing to do with unqualified persons—are content to allow agents and persons without any legal training to prepare legal documents for them. Experience has shown how essential it is that such documents should be prepared by persons properly qualified to do so. Questions involving difficulty and expense frequently arise upon the construction of badly drawn or incomplete documents. It then becomes necessary to seek legal advice, and to incur expense which might have been avoided if a solicitor had been consulted in the first instance.

New Inventions.

A NEW INSTRUMENT FOR USE IN THE RADICAL CURE OF FEMORAL HERNIA.

EXPERIENCE of a modified method of the Roux operation for the cure of femoral hernia in children by using the Jacöel bone staple has made me enthusiastic in its recommendation. The original staple-holder, however, when employed for the operation in adults, is found to be insecure, and the





staple is too easily separated from the holder. I have therefore devised the staple-holder shown in the illustration, the use of which renders the operation more satisfactory. The holder and the staples are made in two sizes—one set for children, the other for adults. The operation proceeds according to Roux, but the sac is utilised as in Macewen's radical cure for inguinal hernia. The ramus of the pubis should be well freed from the pectineus muscle. The femoral vessels should be well retracted outwards to ensure their immunity while the staple is being placed and driven into the bone. X ray examination afterwards will give the appearance of the hip-joint being penetrated by the staple, but there is no danger of this whatsoever. The staple-holder consists of a punch and a screw which, when tightened by a rod, presses on the free plate underneath and firmly grasps the horizontal bar of the staple, while the staple-points are accurately placed so as to enclose part of Poupart's ligament and hammered into the ramus of the pubis. A slight relaxation of the capstan screw by the rod releases the punch. The fluting of the staple prevents it again working loose, thus rendering the one criticism of the Roux operation inapplicable.

Messrs. Down Brothers, Limited, St. Thomas's-street, London, S.E. 1, are the manufacturers.

ALEX. MACLENNAN, M.B., C.M. Glasg.

ROYAL SOCIETY OF ARTS.—Among the many interesting lectures to be delivered this session are two remaining Cantor lectures on Jan. 28th, and Feb. 4th, at 8 P.M., by Dr. Eric Keightley Rideal on Colloid Chemistry. On Feb. 27th, at 8 P.M., Dr. C. S. Myers, F.R.S., will speak on the Use of Psychological Tests in the Selection of a Vocation. On March 12th, at 8 P.M., Mr. Alan A. Campbell Swinton, F.R.S., will give Personal Recollections of some Notable Scientific Men.

UNIVERSITY OF VIENNA.—The *Jewish Chronicle* states that an offer from Mr. Bosel, a Jewish financier, to meet all financial obligations incurred by the State on behalf of Vienna University has been accepted by the Austrian premier. The University budget should thus be restored to the pre-war standard and the University enabled to extend its operations without fear of financial difficulties. An official statement announces that there is no further danger of anti-Semitic disturbances at the University.

THE LANCET.

LONDON: SATURDAY, JANUARY 26, 1924.

SPIRITUAL HEALING: THE CURE AND THE CURÉ.

As an outcome of the Lambeth Conference of 920 the Archbishop of Canterbury appointed a committee to consider and report upon "the use with prayer of the laying on of hands, of the unction of the sick and other spiritual means of healing." Under the chairmanship of the Bishop of Oxford the committee consisted of seven bishops and eight distinguished priests, with Sir CLIFFORD ALLBUTT, Sir ROBERT ARMSTRONG-JONES, the late Prof. W. H. RIVERS, Dr. WILLIAM BROWN, Dr. J. A. HADFIELD, and Dr. JANE WALKER. Their report has now been issued,[1] and is so commendably brief and straightforward that none of the many busy people whom it concerns have any excuse for neglecting it; more than half of the pamphlet is occupied with a learned discussion of the historical aspects of the question by Canon A. J. MASON and Dean ARMITAGE ROBINSON, and with some suggested forms of service.

The committee accepts without reserve the plain fact of experience that the mental attitude of a patient has a great deal to do with the effect and progress, sometimes also with the initiation, of the pathological conditions. The influence of mind on the body, known since the earliest times, was to some extent forgotten and overlooked in the materialistic rise of modern medicine during the nineteenth century. It is little to be wondered at that the flood of new and tangible knowledge which the morbid anatomists let loose led to a misconception of the position which has persisted till quite recent years, and indeed is still pretty widely prevalent. In orthodox medicine disease came to consist of alterations in anatomy or in perversions of physiology, and it became immoral to treat the symptoms which plainly constitute the disease as far as the patient is concerned. But patients are persistent, and there followed a period when medical men had to recognise that there were a good many people who resented the medical attitude of non possumus; though they presented no particular morbid anatomy they had symptoms which did not readily clear up under the rather unsympathetic treatment which they generally received. That time has, however, now passed, and everyone allows that any attempt to distinguish sharply between "organic" and "functional" disease is impossible. The "functional" element is present with every queasy stomach as well as with hysterical palsies, and we have got back again to the rational recognition that among the most important factors in the treatment of disease are the personalities of patient and physician. Thus pastoral medicine becomes of real importance. Extreme views have been held on both sides; it is well to recognise that it is as useless to deny the value to treatment in a case of typhoid fever of that sympathetic environment that promotes faith and confidence, as it would be idle to supply nothing but mental comfort to the victim of a broken leg. (The Minister of Health (see p. 209) hesitates to print a certificate of death alongside the other certificates on the insured person's pink paper, recognising the influence of a sinister suggestion.) The Archbishop's committee sets out clearly the three main lines of healing. With material methods they are least concerned; they point out, however, that their efficacy depends to some extent on the faith and suggestion which are always at work. In psychical methods—re-education, suggestion, psycho-analysis—they recognise a common ground between those who have the cure of bodies and those who have the cure of souls. They commend a fuller knowledge of modern psychology to the clergy, but emphasise their view that nothing like direct treatment should be undertaken except in close coöperation with a good physician. It is in the third department, devotional and sacramental healing, that the special province of the clergy lies, and the committee expresses the opinion that this can certainly achieve complete or partial bodily recovery, though admitting that it has done nothing which has not been done by psychotherapy without religion. But in this therapeusis the healing of the spirit is primary, the healing of the body secondary. Its object is the restoration of the whole man and his elevation to a higher level; this will often include his physical betterment as a by-product. It is not difficult to believe that the committee is right. The serene quiet of those who have achieved a faith in other-worldliness may lead at once to the neglect of any physical crosses which may have been put upon them and to the prevention of those ills which come from the fidgety restlessness of this life. Whether we can at present translate the cheerful serenity of belief into terms of blood pressure or digestion or adrenalin or not, no one will doubt its importance in the prevention and cure of disease.

As for practical procedure, the committee doubts the value of services of healing where considerable numbers of sick people gather together. Treatment is best undertaken individually, and in this prayer should form the first line of approach to be followed, if desirable, by unction (i.e., anointing with oil by a priest), or the laying on of hands (by a priest or a layman), or both. The recognition that particular persons have exceptional powers by the institution of licenced healers is not approved of. It should be noted that Sir CLIFFORD ALLBUTT and Sir ROBERT ARMSTRONG-JONES desire to dissociate themselves from the recommendation of the use of unction. It would be interesting to know their reasons; at the lowest valuation it might prove a useful method of suggestion.

[1] The Ministry of Healing. London: S.P.C.K. 1924. Pp. 43. 6*d*.

THE CAPITATION FEE INQUIRY.

THE Court of Inquiry appointed by the Minister of Health to determine the capitation fee to be paid to insurance practitioners as from Jan. 1st concluded its public sittings last Monday. We understand that the decision of the Court may be expected at an early date. It will be recalled that the original proposal of the Minister was that the capitation fee of 9*s*. 6*d*. should be reduced to 8*s*. 6*d*. for three years, or 8*s*. for five years. The claim of the doctors was that the fee should be from 10*s*. 4*d*. to 10*s*. 9*d*., while the approved societies asserted that a fee in the neighbourhood of 7*s*., certainly not more than 7*s*. 6*d*., was fully sufficient. The Minister admitted that it was a "most complex problem." The Conference of Local Medical and Panel Committees, adopting the recommendation of the Insurance Acts Committee of the British Medical

Association, definitely rejected the Minister's offer of 8*s*. for three years, and requested arbitration on the offer of 8*s*. 6*d*. for three years (failing arbitration this offer, too, to be definitely rejected). The doctors further declared that any agreement with regard to the capitation fee must be subject to a further agreement, which would have reference to the special circumstance of rural practitioners. In conveying their decision to the Minister, the profession expressed every wish towards a peaceful solution, and recalled that, throughout 1923, its representatives had striven for a settlement by consent, and for the cultivation of friendly relations with representatives of approved societies and others interested in insurance administration. The Minister at first refused arbitration, stating that in arriving at this decision he had "regarded his position as that of an arbitrator with the added responsibility of his ministerial duty." When, however, more than 90 per cent. of insurance practitioners placed their written resignation from insurance service in the hands of the Insurance Acts Committee, the Minister made a further proposal in alternative form. He offered either to pay 8*s*. 6*d*. for a period of five years, or to appoint an independent Court of Inquiry, whose finding should be binding on both parties for one year. The second alternative was accepted by the Insurance Acts Committee, and the Court was appointed on Dec. 12th, under the chairmanship of Mr. T. H. HUGHES, K.C. The Court was opened on Jan. 4th, and has held five public sittings. Under the suave direction of the Chairman, the proceedings have, on the whole, been marked by an atmosphere of courtesy and mutual consideration, and the occasional tendencies to introduce irrelevant recriminations have been checked. Most of the evidence showed an intelligent appreciation of the wider principles necessarily involved in the development of a medical service which affects more than one-third of the total population. Particularly significant was the unanimous expression of opinion that the medical profession, as a whole, had conscientiously fulfilled its responsibilities towards the insured population. A considerable weight of evidence supported the view that the insurance service had steadily improved since its inception, and that it offered more complete and efficient medical treatment than was provided under the earlier friendly society benefit systems. The evidence disclosed that the number of complaints which are made against individual doctors is surprisingly small, representing approximately one complaint from every 12,000 insured persons over a period of four years. Such criticisms as were offered were directed largely against the system of certification—the approved societies complaining that their funds are suffering considerable loss through lax certification; the doctors, on the other hand, contending that the existing certification rules are in many respects unnecessarily oppressive and difficult of application.

The evidence submitted to the Court represented four interests—the Ministry of Health, the medical profession, the insurance committees, and the approved societies. The societies who had determined to take no part in the proceedings reconsidered this decision at the last moment, and presented their case after the evidence of the other parties had been concluded. Happily, the fear of "undignified disputes between the doctors and the societies" which had been expressed by the Minister was not realised. Some of the witnesses in their anxiety to safeguard the funds of their societies appeared to ignore the principle that any great scheme of national health development must, in the end, rest upon a willing and satisfied medical profession. But, on the whole, the evidence of the societies while stressing, as it was bound to do, cases of alleged loose certification, acknowledged, in the main, the adequacy of the service which had been rendered to insured persons. The financial case of the societies was based on the pre-insurance contract rate of 4*s*., the contention being that the 7*s*. 3*d*. offered when medical benefit first came into operation represented an unjustified increase on the earlier club practice rate, and that all subsequent calculations—based as they had been on the initial 7*s*. 3*d*.—were excessive. The evidence of the insurance committees for England, Wales, and Scotland unanimously expressed the view that insurance practitioners, as a whole, had faithfully rendered their services to the insured population, and that, with few exceptions, the insured person receives as good a service as is given to other persons in similar positions who pay private fees. In expressing these opinions the committees claimed that, as the statutory bodies entrusted with the administration of medical benefit throughout the country, they were brought into close touch both with the doctors and the insured persons, and were in a position accurately to judge the day-to-day working of medical benefit. The case of the Ministry of Health was mainly statistical. It maintained that the reduction in Civil Service bonus since 1920, consequent on the fall in cost of living, offered a ratio of reduction which could fairly be applied to the capitation rate, and that on this basis, and having regard to the alteration in practice expenses, &c., the offer even of 8*s*. for five years represented a more liberal fee than the mathematics of the case would support. By applying a time rate equivalent, based on the assumption that each insured person requires on the average 3·5 services a year, the Ministry contend that a panel of 2000 insured persons would involve approximately eight visits and 16 surgery consultations each day of a working year of 300 days, and that this should occupy not more than one-half or at most four-sevenths of the doctor's time. The income resulting from such a practice on a capitation fee of 8*s*. 6*d*—£665 net for half-time work—is, in the Ministry's opinion, adequate.

The case for the medical profession was presented by the Insurance Acts Committee of the British Medical Association; the Medical Practitioners' Union gave separate evidence on behalf of its members. The case for the doctors lays stress on the principle that unless the remuneration paid for insurance practice is adequate, and equivalent to the rate of income derived from private practice, the best minds and most suitable personalities will either be attracted to other professions and callings, or will devote themselves to other branches of medical work; that while the profession is anxious that the service given to insured persons should be a full and complete general practitioner service, full recognition must be given to the extended conception of what such a service involves; and that a uniform capitation rate for the country must have regard to the best services and most arduous conditions of practice, and should not represent the lowest sum for which medical attendance on insured persons can be obtained. The doctors believe that the Ministry have overestimated the number of services which the practitioner can with justice to himself or his patients perform, and they dispute the correctness of the Civil Service ratio of reduction. Their statistical case is based on the very complete tables prepared by Prof. A. L. BOWLEY. The case for the doctors was presented with great skill by Dr. H. B. BRACKENBURY, and there will, we believe, be general agreement with the opinion expressed by the Chairman that the profession are fortunate in

aving so able an advocate. Dr. BRACKENBURY was bly assisted by Dr. A. COX. Whatever may be the nding of the Court the medical profession will, e think, be satisfied that, in the hands of the nsurance Acts Committee of the British Medical ssociation, their case has been presented in no narrow pirit of bargaining, but has been based on a knowledge f the full nature of the responsibilities involved in a mplete and efficient general practitioner service. he conviction is displayed that the service can be aintained at the high standard desired by the pro- ssion no less than by the Minister, only if the muneration is adequate both on economic grounds, nd as tending to encourage the progressive usefulness f the service to the nation.

AN ABRAMS INVESTIGATION.

THE January issue of the *Scientific American*, ontaining the fourth instalment of an inquiry into he Electronic Reactions of Abrams (E.R.A.), reached s at the same time as the announcement of his death. Ve gave last week a brief sketch of Dr. Abrams's areer, and in our present issue Dr. Howard Humphris ells the story of his claims and how these claims are upported. Dr. Abrams gradually developed the heory that every illness to which man is heir is due o erroneous vibrations of electrons. He next con- tructed an instrument known as an "oscilloclast" y which these vibrations could be measured and eproduced, and it was then but a short stage for him o restore the normal vibration found in health. n doing so he was able to dispense with drugs, for he ound that effective drugs possessed a like vibratory ate to the diseases for which they are effective. wo courses were open to anyone who became possessed f such momentous discoveries for the good of man- ind. In the first instance the inventor might have emonstrated step by step the scientific principles nderlying the mechanism by which, for instance, the lacing of a dried specimen of blood in a box produces n audible change of percussion note or a palpable oughness of the skin in the reacting medium. To hat extent the timbre of the percussion note is nder the conscious or subconscious control of the ercussor has been impressed upon several generations f clinical clerks, for there are well-known instances here clinicians of great repute and experience have een able constantly to find physical signs which ere never confirmed by the pathologist. Dr. Abrams never attempted to set out the cogency of he sequence of events so as to satisfy the scientific bserver. We understand, however, that he was ccupied shortly before his death with working out method of more objective control. The second ourse open to such an inventor would have been o ask the medical world, accepting for the moment is methods, to satisfy themselves that the results btained thereby do actually correspond to patho- ogical findings. The *Scientific American* found Dr. Abrams unwilling to submit to comparative lood tests on the ground that electronic and clinical iagnosis are two entirely different things. To those nable to confirm his results Abrams simply declared hat their conception of his methods was akin to that f a "Swiss cheese-sandwich replying to questions con- erning the nature and composition of celestial bodies." Ie deliberately removed his observations from a egion where they could be controlled by those brought p in the methods and ideals of medical science. heir interest is psychological and now antiquarian.

INDEX TO "THE LANCET," VOL. II., 1923.

THE Index and Title-page to Vol. II., 1923, which vas completed with the issue of Dec. 29th, is ow ready. A copy will be sent gratis to subscribers n receipt of a post-card addressed to the Manager f THE LANCET, 1, Bedford-street, Strand, W.C. 2. ubscribers wishing to receive the Indexes regularly s published should indicate this desire.

Annotations.

"Ne quid nimis."

VITAL STATISTICS FOR 1923.

THE Registrar-General has issued a provisional statement of the figures for birth-rate, death-rate, and infantile mortality during the year 1923.

—	Birth-rate.	Death-rate.	Infant mortality-rate.
England and Wales	19·7	11·6	69
105 County Boroughs and Great Towns including London ..	20·4	11·6	73
157 Smaller Towns	19·8	10·6	68
London	20·2	11·2	61

The smaller towns are those with an estimated population in 1921 of 20,000–50,000. The death-rate for England and Wales relates to the whole population, but that for London and the groups of towns to the civilian population only. The birth- and infant mortality-rates for London have been provisionally corrected for transfers.

The Registrar-General remarks that the birth-rate of England and Wales as a whole is the lowest recorded, except during the war years 1917–19, while the death-rate and infantile mortality are the lowest on record. These provisional figures, which are not likely to require substantial modification, have been got out for the information of medical officers of health.

THE MENTAL HOSPITALS SERVICE.

WE have been taken to task by a friendly critic for the tone of our comments upon the reports of mental hospitals, and especially for the brief survey of these reports on p. 44 (THE LANCET, Jan. 5th). Allusion was there made to the difficulty of obtaining mental nurses. "Anyone reading this," our correspondent objects, "would think that such difficulties were peculiar to mental hospitals. Of course it is well known that general hospitals, fever hospitals, special hosp tals of all kinds, and cottage hospitals have the utmost difficulty in getting staff, and domestic servants are becoming an unknown quantity." We also alluded to the unduly large proportion of mental nurses, both male and female, who never obtain their certificate, inferring—our correspondent complains—that mental hospitals are to blame, "whereas the serious problem of the hour everywhere is the lack of ambition and of the capacity for steady work in the younger generation." It has been very far from our intention to belittle the work done at mental hospitals. In four instances during last year we took occasion to commend reports as exceptionally full and interesting; on three occasions reference was made to valuable research in progress, and in a dozen at least there were records of therapeutic innovations, amplified staff, and improved equipment. We recorded as noteworthy the practice of one large hospital in allowing large numbers of patients out on trial and on parole, in spite of the added anxiety and trouble involved. Dentists, surgeons, and ophthalmic surgeons had been appointed, in one case an instructor in occupational therapy; X ray plant, pathological laboratories, baths, new wards, convalescent homes, and out-patient departments had been instituted. Wherever such changes as these were put on record we noted and welcomed them.

We fully appreciate the difficulties with which medical superintendents of mental hospitals have to contend, and any adverse comment on the administration of these hospitals which has been made in our columns has been directed towards the removal of some of these difficulties as an essential condition of improved treatment for the insane. It is not within the power of the medical staff to alter them; that power is in the hands of lay committees, and ultimately in those of the ratepayers. Defects in the

service are capable of remedy only by increased expenditure, whether on buildings, salaries, equipment, on the means of recreation, or on food and clothing. Until money is made available for these purposes it is our duty to indicate the directions in which it is needed. The only particular in which the work of medical superintendents has been criticised is not immaterial to the present point at issue. The criticism was this: "It is perhaps not out of place to comment on the very brief and formal style which characterises these reports; it is frequently difficult to gain from them any clear picture of the work which it is their purpose to record. This must always appear as a missed opportunity of enlightening the public, and a few paragraphs which do no more than retail the main statistics in another form, and record minor structural changes and formal acknowledgments, can hardly be said to do justice to the vast amount of patient and careful work performed by the staff of such institutions."

How can the successful features of the year's work at a mental hospital be appreciated when such information is absent from its reports? Further than this, a number of mental hospitals publish no reports at all, and the last available report of the important and numerous institutions under the control of the London County Council was issued in 1922 and dealt with the year 1920. The public and the medical profession are surely entitled to be adequately informed as to the work of these hospitals, whose upkeep is a large item of public expenditure, and whose administration affects the welfare of many thousands of patients.

BLOOD TRANSFUSION IN JAPAN.

A JAPANESE investigator, Dr. Takeo Torii, has recently published in German an account of experiments upon the problems connected with blood transfusion conducted by him during three years at the University of Fukuoka.[1] His investigations divide themselves into two series: (1) experiments on animals with transfusion of incompatible blood, and (2) clinical observations on transfusion of compatible blood in human beings. The results in general do not furnish much information that is new, but they, at any rate, confirm the observations of others. Attention may be drawn, however, to a few points of interest. It has often been noticed that there is an immediate increase, in the recipient's blood, of the red cells and hæmoglobin content, but that a fall occurs soon afterwards. Dr. Torii has found that this is to be accounted for by a temporary "hydræmia" or dilution of the blood which takes place within 3 to 15 hours of the transfusion, both of compatible and of incompatible blood. This observation is of some importance in the interpretations of the rather anomalous results that are sometimes obtained in attempting to estimate the effect of blood transfusion by determining the red cell content. Dr. Torii has also shown that transfusion of incompatible blood produces in the recipient an invariable leucocytosis, in which all the varieties of cell participate. Abnormal white cells also appear and phagocytosis of the foreign red cells can be observed. If the production of abnormal cells be taken as an indication of the degree of poisoning produced, then Dr. Torii has been able to infer that the intravenous injection of foreign red cells is much more powerful in its effect than is the injection of foreign plasma. Some observations on the effects of injecting defibrinated blood are also interesting. The re-infusion of blood from the peritoneal cavity in cases of intra-abdominal hæmorrhage has been often practised in recent years, but some fatalities have been recorded. Dr. Torii has found that the immediate transfusion of the recipient's own defibrinated blood is highly injurious; but that after the lapse of a few hours, or after warming the blood, this effect is not produced. Dr. Torii's clinical observations are perhaps less interesting than those made in the laboratory. He has found the use of citrated blood to be the simplest and safest method. As regards donors, he emphasises the necessity for a very careful choice when repeated transfusions are being given, owing to the fact that any incompatibility that may be between two individuals is heightened by transfusion. Attention is thus again drawn to the fallacy of supposing that the blood of group IV. donors (the "universal donor") can be given indiscriminately. Dr. Torii claims, indeed, to have found that red cells of group IV. are often agglutinated by the serum of group II. blood, though the reaction is much slower and less pronounced than between the groups usually regarded as incompatible. This observation, if correct, is sufficient by itself to dispose of the "universal donor" theory and to explain the slight reactions that are sometimes found to follow the transfusion of theoretically compatible blood. Dr. Torii's list of 231 references is valuable, as it contains many German contributions not recorded by other authors.

THE MECHANICAL TREATMENT OF ACUTE ANTERIOR POLIOMYELITIS.

AT a meeting of the Manchester Medical Society held on Jan. 9th Mr. Harry Platt opened a discussion on the mechanical treatment of acute anterior poliomyelitis. He pointed out that it had long been recognised that the serious disablement resulting from this disease was in many cases dependent on the existence of deformity rather than on the paralysis. Although it was possible at a late stage to correct multiple contractures by surgical measures and to make comparatively helpless children walk in suitable appliances, the surgical problems afforded by these patients would be much simpler if a deformity had been prevented from the first. In spite of genuine advances in the treatment and handling of poliomyelitis in its earliest stages, a mass of neglected cases were still encountered. In geographical areas served by a special hospital, such as exists now in Shropshire, Oxfordshire, and the Lake country, epidemics of acute poliomyelitis could be adequately provided for and the early mechanical treatment of each individual case could be instituted. In the cities, however, the conditions were not so favourable. Delay in applying efficient early treatment is often due to the difficulties of establishing a diagnosis. The clinical syndrome of the early stage of acute poliomyelitis does not appear to be familiar enough to the practitioner of medicine; in enumerating the early symptoms Mr. Platt laid emphasis on the pain and tenderness which are constant features of the initial stage. The treatment to be adopted in the acute stage must be founded on a clear appreciation of the pathological picture of the disease and of the symptoms which such morbid changes evoke. In this condition there is opportunity of applying at the earliest moment classical surgical principles: (1) Rest, for the acute inflammatory lesion. This implies the protection of the inflamed nerve cell from every form of stimulus. (2) Prevention of deformity. (3) The continuous relaxation of completely paralysed muscles. According to Mr. Platt these aims are best achieved by the immediate immobilisation of the child in the recumbent position in an apparatus which maintains fixation of the spine and limbs. There are two methods of effecting this: either the use of a plaster-of-Paris bed, or a well padded frame of the double Thomas or Bradford type. As in the early stages the paralysis is often diffuse, standardised positions may be adopted in which, with certain exceptions, no particular group of muscles are unduly favoured. The hips and knees are kept extended, and the feet placed at right angles. The position of the upper limbs should be right-angle abduction at the shoulder with the forearm flexed at the elbow and supinated, and where necessary, the wrist in dorsiflexion. Once the patient is comfortably installed in his shell he should be subjected to the minimum amount of disturbance

nd this period of complete immobilisation should utlast the stage of pain and tenderness. With the nset of muscle recovery the degree of fixation of the ody should be lessened, and the patient gradually rought into the sitting position; the affected mbs should be maintained on splints or in the emains of the plaster shell for a much longer period ntil walking is attempted. Further, the splints ould be worn as night splints for at least another wo years. When these precautions are taken the ask of re-education which follows the stage of immo- ility becomes much easier.

YEAST AND CONSTIPATION.

YEAST is an old remedy for constipation, and ome recent investigators have thrown doubt on its fficacy. However, in the current number of the *Journal of Pathology and Bacteriology* (vol. xxvii., . 42) Dr. Louis Gross, of Montreal, working in ondon with a Beit fellowship, describes experiments n rats of a very striking character. Animals were ed with normal diets and diets deficient in A and B itamins, and the activity of the alimentary canal as determined by giving a dose of charcoal and iming its first appearance in and its final disappear- nce from the stools. In one rat on a normal diet he charcoal appeared in nine hours and had entirely lisappeared in 65 hours; the same animal on the ame diet without marmite (an extract of yeast) howed the first appearance of charcoal in 12 hours, nd it was still present after 16 days. Afterwards he same animal on the full normal diet with marmite ot rid of the last of the charcoal in five days. Similarly a rat on normal diet passed 13 or 14 scybala a day, which fell to two or three a day after a fortnight without marmite; administration of small quantities f marmite soon restored the normal number. Dr. Gross points out that the delay in the passage of the charcoal cannot be explained by a lower consumption of food owing to the loss of appetite characteristic of deficiency in vitamin B, since the intake during the normal period was limited to the amount eaten during the period of B deficiency. The action of marmite does not seem to be direct and local, since n experiments on rats' intestine in vitro it had, if anything, an inhibitory effect on motion. Similar experiments on animals fed on diets deficient in vitamin A showed a marked acceleration of the passage of food through the alimentary canal. The author could detect no definite anatomical or histological changes which could be correlated with these results, failing to confirm both Colonel R. McCarrison's description of changes in Auerbach's plexus in B deficiency and Dr. W. Cramer's description of mucosal atrophy of the intestine in A deficiency. But he has adduced a good deal of evidence connecting intestinal stasis with absence of vitamin B in the diet.

MEDICAL HYDROLOGY IN ENGLAND.

IN our correspondence columns will be found an influential letter containing definite proposals for the promotion and teaching of medical hydrology in this country. These have been laid before the Ministry of Health, for the committee in charge regard as essential the recognition of hydrology and of the spas by the Government. University teaching alone cannot give the necessary stimulus and scientific coördination. The current issue of the *Archives of Medical Hydrology* recalls the large scale on which physical remedies were used for disabled men; this fine service of British spas has perhaps hardly been sufficiently recognised. A course of lectures on medical hydrology was given last year at London University, and a preliminary circular has just been issued of the next course to be held in the week commencing May 5th, with a study tour to Bath and Cheltenham. Lectures are also contemplated at provincial universities. Efforts to secure teaching of this subject in England date back many years. Some members of the present committee coöperated in 1897 with the late Dr. Theodore Williams and Dr. Alfred Havilland in circulating to the medical schools a programme of instruction in hydrology and climatology. A committee, including leading spa physicians and many other well-known names, laid a memorial in 1914 before the Senate of the University of London, detailing the elaborate teaching in foreign universities and asking for central teaching in London and a chair of hydrology and climatology. The war intervened to prevent this scheme maturing. The present committee is the fourth that has handled the matter, and we hope that its present proposals will meet with acceptance.

CANCER DEATH-RATE IN IRELAND.

THE quarterly return [1] of the Registrar-General of the Free State for the third quarter of 1923 shows a commendable regard for continuity of records, now that Irish vital statistics need to be studied in two separate official reports, for appended to a statement of deaths and causes of death in each of the 56 urban districts in Leinster, Munster, and Connaught, and the 10 urban districts in Ulster which are within the Free State, corresponding figures for the cities of Belfast and Londonderry are given by courtesy of the Registrar-General for Northern Ireland. Perhaps at the moment the most interesting death-rate is that from cancer which was only 71 per 100,000. This is a crude death-rate not corrected for age- and sex-distribution of population. The average age of the population of Ireland is greater than that of England, and other things being equal its cancer death-rate should be higher than that of England, whereas the official figures show a much lower cancer death-rate. This is no new phenomenon, the standardised death-rate from cancer in Ireland many years ago having similarly been increased by correction for age- and sex-distribution of population. Even when this correction is made cancer appears to be less fatal in Ireland than in England: and further investigation into the local incidence of cancer in Ireland, and concurrent inquiry which might elucidate inter alia whether to a considerable extent differences in official death-rates are ascribable to variations in accuracy of medical diagnosis and of medical certification, would be likely to elicit valuable information in other respects. As bearing on completeness of certification, it may be noted that medical certification is commonly more exact for deaths in institutions. Such deaths from all causes numbered 28·4 per cent. of the total deaths in Ireland in the second quarter of 1923, while in Dublin they numbered 45·1 per cent. of the total number.

COLLOID PHENOMENA IN BACTERIOLOGY.

To the fifth report on colloid chemistry of the Department of Scientific and Industrial Research,[2] Dr. E. K. Rideal contributes a suggestive article upon certain phases of bacterial activity. He begins by discussing the phenomenon that bacterial growth in fluid media is self-limiting; when, however, any culture has ceased to progress and the bacteria are separated by centrifuging, these are still capable of growing in a new medium, whilst, on the other hand, the old medium is still capable of providing pabulum for a fresh inoculation of the same bacteria. It is suggested that this is due to the inhibition of the original bacteria by surface adsorption of products of growth such as alcohols, soaps, or fatty acids. Bacteria in a fluid may be regarded as forming a colloidal system and with the large surface development of such a suspension, adsorption at the interface between the two phases becomes an important factor in the distribution of substances in solution. Any substance lowering the interfacial tension—in accordance with

[1] No. 239. Edson and Son, Ltd., 40–41, Lower Sackville-street, Dublin. Price 6*d*.

[2] British Association for the Advancement of Science. Fifth report on Colloid Chemistry and its general and industrial applications. London: H.M. Stationery Office. Price 2s. 6d.

a well-known physical law—will be distributed in greater concentration at the interface in question, in this case the bacterial envelope, than in the suspending fluid. Dr. Rideal suggests that the self-limitation of bacterial growth depends upon the production by bacteria of metabolic products, which have this effect upon the surface tension and thus become concentrated upon the bacterial surface; these substances, being in their way excretory products, are unfavourable to the organism's growth and nutrition, which finally ceases to progress. Upon removal to fresh medium, the equilibrium is upset and the adsorbed substances are to some extent desorbed, allowing growth to occur again. Fresh bacteria can grow in the old medium for a short time because the concentration of these substances in its bulk is not sufficiently high to be inhibitory. It is not possible to put this hypothesis to experimental proof by measurement of the interfacial tension between bacteria and medium, but it is easy to measure the medium air interfacial tension which in many cases will probably have a value relatively similar. It is found that with a range of antiseptics, from thymol to phenol, the effect upon the surface tension is accurately correlated with antiseptic activity, which suggests the presence of an adsorption factor on these lines. The question of the selective adsorption of the various products presented to bacteria is, in its ultimate analysis, a chemical one, depending upon the presence in the bacteria of reactive groups capable of combining with those available in the dissolved substances of the circumambient fluid.

CONJUNCTIVAL INFECTION WITH TUBERCLE.

IN 1913 A. Calmette and his fellow workers drew attention to the possibility of infecting guinea-pigs with tubercle bacilli by the conjunctival route, and it was thought that a clue had been found to the genesis of the cervical adenitis of childhood. Though the virus transmitted through the conjunctivæ spread to the cervical glands, the tracheo-bronchial glands, the lungs, and abdominal viscera, lesions at the level of the eye itself were never observed. We alluded briefly last week to similar investigations conducted by Prof. S. Lyle Cummins with results that did not in every respect tally with Calmette's. Prof. Cummins found [1] that a definite local inflammatory reaction in the eye itself usually occurs but is very late in appearing. Of two guinea-pigs infected by the conjunctival route, one (No. 125) was a normal animal, and the other (No. 123) had been inoculated a month earlier with tubercle bacilli of low virulence. In this animal acute conjunctivitis developed a day after the conjunctival instillation, whereas in the case of No. 125, the conjunctivæ did not become inflamed until the third week after the instillation. It would seem that the rapid onset of acute conjunctivitis in the animal already infected with tubercle bacilli of low virulence was due to an allergic state induced by the earlier infection. Comparisons made between the effects of subcutaneous injection and conjunctival instillation of tubercle bacilli brought out one very interesting point. Among the guinea-pigs given subcutaneous injections of varying quantities of tubercle bacilli, there was no appreciable difference in the reaction, whether 2000 million or only 2000 bacilli were injected. But when the bacilli were introduced by the conjunctival route, the course of the disease varied according to the dose; it was rapid and acute when a concentrated emulsion of tubercle bacilli was instilled, and chronic when dilute instillations were given. These observations give support to the hypothesis that in the tuberculosis of man the massiveness of infection plays an important part. The condition of the child whose only apparent defect consists of enlarged cervical glands may be compared with that of guinea-pig No. 125 which seemed to be in excellent general health six months after conjunctival infection. When killed it was found to have lesions strictly limited to the infected eye and the cervical glands, which were fibrotic and contained limited areas of caseous degeneration. Prof. Cummins suggests that artificial per-conjunctival infection should help to elucidate many of the phenomena of tuberculous infection and resistance, although the constant association of eye lesions with the cervical adenitis in guinea-pigs indicates that the tuberculous processes in the guinea-pig and man are not strictly similar. And his suggestion is worth following up.

[1] Tubercle, January, 1924.

THE TREATMENT OF NEURO-SYPHILIS.

THE issue in the discussion before the Medical Society for the Study of Venereal Diseases, reported in THE LANCET of last week, on the diagnosis and treatment of neuro-syphilis, turned largely on the value of tests applied to the cerebro-spinal fluid as a guide to prognosis and treatment. Dr. Gordon Holmes, who opened the discussion, contended that the diminution of the cell content often quoted as a sign of improvement might be due to repeated lumbar puncture, since some of the cells in the lower part of the cord are drawn off at each puncture, and the proportion found in the later counts thus reduced. Dr. Holmes confessed to have made more than one serious mistake through being guided by changes in the cerebro-spinal fluid. As to treatment he maintained firmly that the study of this fluid formed no reliable guide to the efficiency of treatment or prognosis in neuro-syphilis, except in interstitial syphilis. Colonel L. W. Harrison, as President of the Society, took up this point in a reasoned comment on Dr. Holmes's opening address. He expressed himself as anxious to accept what he understood to be Dr. Holmes's view that lumbar puncture was not so necessary for the control of treatment of cases of syphilis as our American colleagues would have us believe. Many held that no case of syphilis could be considered to be properly managed unless the treatment were controlled by examinations of the cerebro-spinal fluid, and this view entailed the difficulty that, with all precautions, lumbar puncture was apt to be followed by severe headache, which raised great practical difficulties for the ordinary patient. Perhaps the point raised by Dr. Holmes as to the effect of intensive treatment on the development of the neuro-recidive might be cleared up by the experience in treatment centres as to the number of cases of neuro-recidive which they have seen amongst soldiers treated for syphilis during the war. There were approximately 100,000 cases of syphilis treated in military V.D. hospitals in that period, most of them by a short, rather intensive course. Through the medium of this Society, statistics on this point might be collected during the next few years from medical officers of treatment centres, neurologists, and practitioners who had come across cases of neuro-recidive amongst soldiers treated for syphilis in the war years. Particulars of the actual treatment administered would be necessary, as well as of the nature of the present disease.

POST-OPERATIVE DENTAL TREATMENT OF CLEFT PALATE.

A RECENT paper [1] by Mr. A. T. Pitts on the Orthodontic Treatment of Cleft Palate Subsequent to Operation contains much information that will be found useful, not only by dentists but by surgeons and general practitioners. Mr. Pitts thinks that some surgeons have not realised that the coöperation of the dentist is absolutely necessary to get the best results in the treatment of cleft palate, and there is doubtless much truth in this contention. Surgeons who are accustomed to operate much for this deformity know how difficult it often is to get parents to see the necessity for dental treatment and for training in articulation, in the case of children who have

[1] British Dental Journal, Dec. 15th, 1923.

ndergone operations for cleft palate. They are too ot to imagine that as soon as the cleft has been osed by operation there is nothing left to be done. lr. Pitts divides dental deformities in cleft palate ito two groups: those which are due to the cleft alate itself and are indeed a part of the condition, ough not manifest until the teeth erupt; and eformities of the dental arch which result from the peration and do not exist in a case of cleft palate hich has not been operated on. He is fully justified i his statement that dental irregularities after opera- on, when occurring in the molar and premolar gions, are due to the operation, while irregularities i the incisor region are an original defect of the ongenital failure of growth, but are apt to be increased s the result of operation. At the Hospital for Sick hildren, Great Ormond-street, Mr. Pitts has had iany opportunities of studying the results and omparative merits of the two principal types of peration for cleft palate performed in this country—amely, the Langenbeck or Fergusson operation, and he so-called "flap" operation, usually associated ith the name of Sir Arbuthnot Lane. The two perations lead to different types of dental deformity hich can be readily recognised. Good illustrations f both are given. It is interesting to note the author's onclusion that the irregularity after the flap operation s generally more severe than that caused by the angenbeck operation, and being unilateral is less menable to dental treatment than the bilateral ontraction following the Langenbeck operation. n this opinion he will be supported, we think, by the reat majority of surgeons who have had opportunities f seeing the actual results of both operations. Ir. Pitts discusses fully and fairly the aims, objects, ossibilities, and limitations of orthodontic treatment of left palate subsequent to operation, and deals at length vith the technical means to be employed. Several triking illustrations are given of dental deformities efore and after dental treatment at the hands of imself and his colleague, Mr. William Ovey. The rticle, which is the result of much painstaking esearch and observation, will repay careful study by lentists and by surgeons who are interested in this mall but difficult branch of work.

"PUNCH" AS AN ANTHROPOLOGIST.

AT the second social evening of the session on Jan. 16th Sir Arthur Keith, F.R.S., delivered an ntertaining address on this subject to the Royal Society of Medicine at 1, Wimpole-street, in place of Dr. Arnold Chaplin, who, as had been previously announced, was unable to be present through illness. Sir Arthur Keith said that he was not going to consider *Punch* as a humorist, but would speak of him as a sober man of science—in other words, as an anthropologist. All of us, he said, became anthropologists as soon as we ceased calling every one "dada," and our scientific attainments increased at the school age to the point of recognising friends and enemies from the back or the front. Later, about 15, we could judge the ages of the people we saw, and so on. It was with anthropology of this sort that the speaker wished to deal—a living and practical science, not a dry-as-dust measuring of skulls and angles. And of all British text-books on this subject, he added, the best was the files of *Punch*. Considering the *Punch* artists as being in dead earnest, and unconcerned with the jokes attached to their drawings, Sir Arthur Keith showed on the epidiascope many examples of their work with which he illustrated his subject. The first series consisted of a set of studies of father and son by many different artists, in which the immature features of the son—small nose, slight eyebrow ridges, thin neck, &c.—were shown fully developed in the father, while the type remained unchanged. He then showed how age was indicated on a face, and mentioned that the nose told age changes as well as any other feature up to 55 years of age, but mobile parts, the eyelids, eyebrows, and lips, showed most change. In the course of facial development the nose often seemed to follow a system of growth on its own—that feature might be well-developed, while the forehead and chin remained infantile. Per contra, in a face with powerful jaws and heavy eyebrow ridges the nose might be small and weak. The lecturer then gave an interesting comparison of the primitive broad physiognomy and the modern long narrow face with open orbits. The modern shape, typical in the Englishman, did not probably exist, he said, before Roman times. *Punch* was very fond of contrasting the long face with the broad face—as many drawings exemplified. After a series of pictures illustrating various forms of English round heads, short and long, Sir Arthur Keith showed Mr. Punch himself to have a typically square Teutonic cranium. The chair was taken by Sir William Hale-White, President of the Society, who moved a hearty vote of thanks to the lecturer.

PROF. H. J. HAMBURGER.

BY the death of Hartog Jacob Hamburger on Jan. 4th Dutch science has suffered a severe loss, for Prof. Hamburger was not only a first-rate physiologist, but a chemist who opened up new vistas of knowledge. A pupil of Boche, Mulder, and Dibits, before graduating in mathematics and physical science, he became assistant to Donders, and this contact with medical biology was decisive for his further career. Within six years he obtained his second doctorate in medical science. He then was appointed lecturer in physiology and pathology at the Government Veterinary School, and in 1901 professor of physiology at Groningen University, a chair which he held until his death. It was his happiness to plan and to see erected a new physiological institute, which was admired by physiologists from all over the world on the occasion of the Ninth Physiological Congress, at which Hamburger presided. Among his publications the best known were: "Osmotischer Druck und Ionenlehre in den medizinischen Wissenschaften," and "Physikalisch-chemische Untersuchungen über Phagocyten." His discourse on Permeability in Physiology and Pathology, delivered in London[1] under a scheme of lecture exchange, summed up the results of a life-work on the borders of cellular physics. Much of this work of Hamburger and the group of assistants whom he attracted is accessible in the "Researches from the Physiological Laboratory of the Groningen University," published in 1920.

Hamburger took his full share in national and international scientific intercourse. In 1896 he became a member of the Dutch Royal Academy of Science, in 1909 he received an honorary doctor's diploma at Aberdeen, in 1922 a similar honour at the Veterinary University of Utrecht. In 1908, on the twenty-fifth anniversary of his doctorate in chemistry, a special number of the *Biochemische Zeitschrift* was devoted to his work. At the invitation of Baltimore University he inaugurated in 1922 the Dohme-Foundation. His colleagues in all parts of the world will keep in thankful remembrance "the little kind artless scholar," as he was called in Groningen.

THE new Minister of Health, Mr. John Wheatley, has had opportunity during the course of his career for acquiring close knowledge of some of the most important problems with which he will be called upon to deal. Until the age of 22 he worked as a coal-miner, and since then has had administrative experience in Glasgow and in Lanarkshire. His strong feeling on the need of maintaining adequate support for maternity and child-welfare and for measures directed against tuberculosis was made manifest in a stormy debate in the House of Commons last summer, and his interest in the housing question may be judged from the fact that he is President of the Scottish Labour Housing Association. We wish the new Minister good fortune in furthering the aims he has at heart.

[1] THE LANCET 1921, ii., 1039.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

LV.—TREATMENT OF ACUTE OBSTRUCTION DUE TO GROWTHS OF THE COLON.

IF rectal cases are excluded, one of the commoner causes of acute intestinal obstruction, when it occurs in patients of middle or advanced age who have long experienced abdominal discomfort, is a neoplasm of the colon. The growth is usually a carcinoma situated in the pelvic colon, the beginning of the ascending colon, or one of the flexures; growths in the first-named site being by far the most common. The type of growth varies to some extent with its position, growths in the cæcal region forming large exuberant masses within the cavity of the bowel, whilst a narrow constricting fibrous ring is usually found in the pelvic colon. These growths differ from carcinomata found elsewhere in certain respects: (1) They grow more slowly and are confined to the limits of the bowel for a long time; (2) they are subject to degenerative changes; (3) they do not infect the lymphatic glands in the early stages; and (4) they produce metastases in distal parts only quite late in the disease. A theoretical consideration of these facts leads to the conclusion that malignant disease of the colon, as compared with carcinoma elsewhere, is a particularly favourable disease for operation, and this is amply confirmed by the results of actual practice.

Symptoms.

These patients give a few months' history of malaise, anorexia, and vague abdominal discomfort. There is usually some loss of weight, but this is not a marked feature. Attacks of wind with colicky pains occur with some exaggeration, for the time being, of the gradually increasing constipation which may be, but is not necessarily present. The discharge of fæcal-stained mucus (false diarrhœa) and blood, characteristic of rectal cancer, is uncommon. The actual attack of acute obstruction occurs rather suddenly and is often preceded by a few days' increased difficulty with the bowels. Severe and diffuse abdominal pain with some nausea or actual vomiting indicate the beginning of the crisis. One loose motion may occur as the bowel distal to the growth empties itself, but after this constipation is absolute and no flatus is passed. The patient looks ill, with sallow complexion, dark hollows round the eyes, sunken cheeks and zygomatic fossæ, and foul tongue and breath. The pulse is frequent and of poor volume, the temperature possibly subnormal. If vomiting occurs, bile-stained or fæculent-smelling fluid floods up into the mouth with little apparent effort. The abdomen is distended and, if the walls are wasted, coils of intestine may be seen undergoing irregular peristaltic movements which possibly subside always in one situation, the actual site of obstruction. The abdomen differs from that of a general peritonitis in that it is neither rigid nor tender. There may be local rigidity and tenderness over the site of the growth, but the latter is seldom palpable through the distended abdomen. Occasionally a large lump, *freely movable from side to side*, may be detected in the cæcal region. The preceding few months of abdominal discomfort culminating in the sudden attack of absolute constipation, which cannot be satisfactorily relieved by repeated enemata (ox gall ℥ss ad Oj or turpentine ℥j ad Oj are the best to employ), makes the diagnosis of an organic obstruction certain. *In these circumstances an aperient should never be given.*

If rectal examination and careful inspection of the hernial orifices are negative, then a diagnosis of malignant disease of the colon is probably the correct solution of the problem. It must be remembered, however, that very similar symptoms, usually of longer duration, are produced by papillomata, often multiple and occurring in groups, and especially liable to produce attacks of recurring intussusception of the gut. Particular attention should always be paid to the femoral rings, in which situation it is easy to overlook, and, indeed, sometimes impossible to detect, a small strangulated piece of intestine in a stout patient.

Principle Guiding Treatment.

The essential thing to remember in the treatment of these patients is that no matter whether they are operated upon or whether they are left alone, they will die inevitably unless full exit is given to the intensely toxic fluid filling the intestine. *Moreover, any attempt to excise the growth and perform an anastomosis at this time will be invariably fatal.* Not only will the intestine be unable to pass on its poisonous contents, but leakage, early or late, will occur at the new junction. A piece of bowel in an acute state of inflammation, sodden with œdema, with its thick hypertrophied muscular walls in a condition of great irritability, is most undesirable material to utilise for an anastomosis.

If the patient is desperately ill the quicker and simpler the operation, provided that it is effective, the better the prognosis. When there is a certain amount of asymmetry in the abdominal distension and a visibly distended cæcum coincides with a relatively flat left iliac fossa, a small incision in the right iliac region will suffice. The distended cæcum is not withdrawn from the wound but is carefully sutured to the parietal peritoneum, and a fair-sized Paul's tube fixed in the bowel. It is wiser not to attempt to pass an exploring hand into the abdomen. If, on the other hand, the abdominal distension is of uniform character and there is no evidence as to the site of the obstruction, a para-median incision below the navel may be necessary. A suitable piece of bowel on the proximal side of the growth is selected, one angle of the exploratory incision being utilised or a new small additional incision, made in an appropriate place, for the performance of a colostomy. The bowel is fixed to the skin and a Paul's glass drainage-tube sewn into it.

If the patient's condition is reasonably good certain alternatives are open to the surgeon, depending largely on the site and operability of the growth.

Growths situated in a Movable Part of the Colon.

Operable growths situated in a movable part of the colon, such as the transverse or pelvic portion, are best treated by Paul's operation. A considerable loop of bowel containing the growth in its convexity is brought completely out of the abdomen and fixed either in the exploratory opening or in another one suitably planned. A thick mattress suture passed through the mesentery of the exposed loop from edge to edge of the incision and two fixing stitches at the angles of the wound will suffice for this purpose. If the colon is not sufficiently mobile to allow of this being done without tension, much can be effected by an incision through the lateral layer of its mesentery, where the latter is reflected on to the parietes, and the gradual stripping medianwards of the bowel and median leaf of the mesentery, carrying vessels and lymphatics, with fingers and gauze. A Paul's tube is sewn into the proximal limb of the U-shaped loop. One week or ten days later, when the patient has recovered from the immediate effects of the acute attack, the loop of bowel and the exposed portion of its mesentery are cut away with cautery or knife. Three months or so later the resulting colostomy is closed by an extra-peritoneal procedure, which leaves the new anastomosis lying between the peritoneum and the deepest muscular layer of the abdominal wall. This method is by far the safest of any. It may be urged that a grossly inefficient removal of the mesentery and its possibly infected lymphatics is secured, and this cannot be denied. In practice, however, it is an operation which is found to give most satisfactory results.

Growths situated in a Fixed Part of the Colon.

The cases in which Paul's operation is not suitable may be divided into two classes: (*a*) Those in which on exploration the growth is found to be an operable one—i.e., a movable tumour without evidence of

tensive lymphatic infection or other metastasis; those in which the growth is inoperable.

(*a*) In operable cases the bowel must be at once lieved by some variety of colostomy or cæcostomy. aring in mind that the growth will have to be sected and an anastomosis performed through a nvenient incision made directly over it some two to ree weeks later, the site of the drainage operation ll be so designed that it is some distance away from is point. The advantage of cæcostomy over lostomy is that if, in the former, the gut is merely ed to the peritoneum and not to the skin of the dominal wall, there is quite a reasonable chance at the fæcal fistula will close spontaneously at a later ite, when its services are no longer required. In old atients and in those whose tissues are in a poor state nutrition, a third and fairly simple operation may ve to be performed for its closure.

(*b*) In cases where the growth is inoperable, the oice lies between short-circuit and colostomy. The tter is undoubtedly the safer procedure, and where a ft inguinal or transverse colostomy is possible, this ould be done. In cases in which a cæcostomy alone ould be effective (i.e., growths of the ascending colon hepatic flexure), the surgeon, thinking of the future id the intense discomfort of a permanent cæcostomy ith fluid contents leaking continuously, will probably cide upon some form of short-circuit. If the bowel not too greatly paralysed the risk to life of this ocedure will be more than compensated for by the eatly increased future comfort of the patient. The orter the stagnant loop of the short-circuit, the tter will be the ultimate result.

In these external drainage operations the intestinal ntents will usually at once begin to flow away, but in unsatisfactory amount calomel in doses of gr. ss ould be given every hour until the desired result is btained. The skin around a cæcostomy suffers from e toxic fluid which pours over it continuously, and ould be protected by a thin smear of ung. zinc oxid. ade sufficiently fluid by the mixing into it of a little stor oil.

Harold W. Wilson, M.S. Lond., F.R.C.S. Eng.,
Surgeon, with Charge of Out-patients,
St. Bartholomew's Hospital.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. E. F. Ellis is placed on the ret. list with the nk of Surg. Capt.

Surg. Lt. H. Hurst to be Surg. Lt. Comdr.

ROYAL ARMY MEDICAL CORPS.

Lt. C. A. Hutchinson to be Capt.

Temp. Capts. relinquishing their commns. and retaining e rank of Capt.: A. S. Blackwell and G. A. Shiel (on ccount of ill-health).

TERRITORIAL ARMY.

Capt. J. M. MacKenzie, R.A.M.C., to be Div. Adjt., 0th (Northumbrian) Div., vice Capt. (Bt. Maj.) R. E. arnsley, R.A.M.C., vacated; and Capt. J. D'A. Champney, .A.M.C., to be Div. Adjt. 53rd (Welsh) Div., vice Maj. . White, R.A.M.C., vacated.

Capt. J. C. C. Howe (late R.A.M.C.S.R.) to be Capt.

Lt. J. Cohen, from 13th Bn., The Lon. R., to be Lt.; and . C. Crawford to be Lt.

ROYAL AIR FORCE.

E. G. Howell is granted a short service commission as light Lt.

Lt. G. A. Ballantyne, Dental Surgeon, General List, rmy, is granted a temporary commission as a Flying fficer on attachment to the R.A.F.

Manchester Royal Eye Hospital.—This hospital has been in existence for 109 years and at the annual meeting the report for 1923 was presented. During the year the out-patients numbered 30,502 and in-patients 046, while the accidents which necessitated treatment at the hospital averaged 23 per day. Various donations and bequests received during the year enabled the managers to reduce the bank overdraft from £9000 to £3000.

THE CAPITATION FEE FOR INSURANCE PRACTICE.

Concluding Sessions of the Court of Inquiry.

The Court of Inquiry appointed by the Minister of Health to determine the capitation fee to be paid to insurance practitioners from Jan. 1st, 1924, held its concluding sessions at the Ministry of Health on Jan. 15th and 21st. The Court was mainly occupied with the evidence submitted on behalf of the approved societies. The members of the Court are Mr. T. R. Hughes, K.C., Chairman, Mr. F. C. Goodenough, and Sir Gilbert Garnsey, K.B.E.

Tuesday, Jan. 15th.

Before the evidence on behalf of certain individual approved societies was taken, Mr. H. F. Jeffrey, Secretary to the Scottish Board of Health, made a further statement regarding contract practice in Scotland. He said that the fee to be paid to doctors for the treatment of miners' dependents had been reduced, as from that day, from 4½*d.* to 4*d.* a week. There was a material difference between the apparent and actual pay which a doctor got for this class of work. There were many unpaid contributions owing to unemployment and there were also the management expenses of the clubs which were a first charge on the contributions and represented about 2½ per cent.

In his reply Dr. Cox stated that the agreement with the miners provided that full contributions should be paid during times of unemployment. There was a medical examination before entry into the scheme; and extra charges were made for special services and expensive drugs. The insured person, assisted by grants from the Exchequer, was in a position to pay an economic rate to the doctor, but this was not the case with many of the dependents.

The National Deposit Friendly Society.

Mr. Tuckfield presented the case for the National Deposit Friendly Society, which claims to be the largest centralised friendly society, having nearly 2300 branches throughout the country with a total membership of 445,000 insured persons and 600,000 deposit members. As regards the medical benefit provided to members outside the national insurance scheme the society did not appoint doctors; they allowed members to select any registered practitioner and made an allowance (based on a scale of charges) in respect of the medical treatment actually received. From 1911 to 1919 the scale for medical attendance and two days' supply of medicine had been 2*s.* 6*d.* for a visit at the patient's house and 1*s.* 6*d.* for a surgery attendance. In 1919 the scale had been increased to 3*s.* 6*d.* and 2*s.* 6*d.* respectively. For a further two days' supply of medicine an extra allowance of 1*s.* 6*d.* was made. Replying to questions by the Chairman, Mr. Tuckfield said that his society had no complaint to make as to the medical attention which had been given to their National Insurance members. They had, however, to deal with complaints of inadequate surgery accommodation, the improper charging of fees, and the giving of irregular certificates. He could not say how many of their 445,000 members had complained. In reply to Dr. Brackenbury, witness said that probably not more than 5 per cent. of the doctors' bills received by members were in excess of the scale authorised by the society.

Dr. Gordon Ward pointed out that, as it was customary to prescribe a four days' supply of medicine, the scale of fees really amounted to 5*s.* and 4*s.* for a visit and surgery attendance respectively. Sir Thomas Neill replied that if one allowed 1*s.* 6*d.* for the first two days' medicine the fee for the actual medical attendance was only 2*s.* and 1*s.* respectively

Northumberland and Durham Miners.

Mr. E. Harrison gave evidence on behalf of the Northumberland and Durham Permanent Relief Fund Approved Society, which had a male membership of 98,000. The society's evidence stated that the present service was satisfactory and equalled that given by general practitioners to the same class of patients in pre-insurance days. The majority of panel doctors gave their patients the full benefit of their knowledge and experience and could not give more. The regulations fully safeguarded the interests of both the doctors and the insured persons. The medical service, as a whole, was quite satisfactory, and the ranks of the panel practitioners were largely filled by men whose skill, character, and attention were all that could be desired. During the past three years the society's officials had visited 13,000 members in receipt of benefit and in no case had there been any complaint against the doctor. There were occasional complaints as regards surgery arrangements, and the difference in the standards of treatment given to insurance and private patients, but the complaints frequently arose out of circumstances over which the doctors had no control.

Certification was not satisfactory. He did not suggest that the doctors had any intention to mislead the society, but in fact the doctors did in many cases fail to give an absolutely true certificate. He admitted that it must sometimes be difficult to say whether a patient is incapable of work, but he thought that all doctors did not fully appreciate the seriousness of a false certificate; his main desire was that doctors should refuse to issue irregular certificates at the request of their patients.

As regards the amount of the capitation fee, witness entirely disagreed with the Minister's figure of 8*s*. 6*d*.; he thought that was too high; it was based on the figure of 7*s*. 3*d*. which was, in his opinion, wrongly fixed when the Insurance Act came into operation. His experience of pre-war contract practice suggested that the usual fee was 4*s*. with medicines. He thought that too low a figure, and he would assume a pre-war fee of 4*s*. 6*d*. to 5*s*. to be fair; applying the calculations of the Insurance Acts Committee that would be equivalent to a fee of from 6*s*. 7*d*. to 7*s*. 4*d*. to-day. He suggested that a fee of 7*s*. was sufficient to build up a fund which could provide an adequate medical service throughout the country. He would be satisfied, if necessary, with a gradual reduction of the capitation fee spread over a term of years. Replying to the Chairman, witness said that they accepted the Ministry's figures of 3·5 services per insured person per annum as an average throughout the country. The figures for his society were 2·3 attendances and 3·1 visits, a total of 5·4, but this included many compensation cases. On these figures, and assuming a capitation fee of 7*s*., a doctor with 1500 patients would give 27 attendances on 300 days a year for a gross income from insurance practice of £525. In reply to Dr. Brackenbury, witness admitted that even the figure of 5·4 services per year referred only to attendances on persons who were incapacitated. Dr. Brackenbury suggested that, at a low estimate, an equal number of surgery attendances must be given to persons not incapacitated; this gave a total of 7·7 services per year; although the service figures in colliery areas were known to be high, the profession suggested that that must be taken into account in determining a uniform fee for the country. In colliery districts there was often little or no private practice.

Pre-Insurance Contract Rates.

Mr. George Wright gave evidence on behalf of the National United Order of Free Gardeners Friendly Society. He said that his society had branches in different parts of the country and that, prior to 1912, they had provided medical treatment and medicines to their members at contract rates which varied from 2*s*. 6*d*. to 5*s*. per member per annum, with an average of 3*s*. 11*d*. With few exceptions the doctors had been very satisfied with that rate. The contract rates paid at present for attendance and medicine to members who were not insured persons varied widely in different districts; thus, in East Yorks alone the rate for adults varied from 4*s*. 9*d*. to 13*s*. 6*d*. In Lancashire it was from 8*s*. 6*d*. to 13*s*. in Northamptonshire and Staffordshire it was 10*s*. He could not say why the rate varied so widely; in some cases, no doubt, the doctors were particularly considerate. The treatment given under the national insurance scheme was, in his opinion, an improvement on the pre-insurance contract practice. He thought that regard should be had to the large number of insured persons who were not on the list of any doctor, yet in respect of whom capitation fees were, presumably, paid into the Central Pool. Thus, in Cheshire alone, 22,133 insured persons had failed to be placed on an insurance doctor's list. It was very probable that many of these were actually receiving treatment from insurance doctors as private patients. As to the amount of the capitation fee it should be remembered that the capitation fee was an average fee to be paid for an average service. The approved societies desired to see the profession properly paid, and the insurance work done by satisfied doctors, but this result should be attained without payment of an unreasonably high fee; in his opinion it should not be higher than 8*s*.

Dr. Cox, in the course of examining the witness, stated that from 1903 to 1910 the British Medical Association had engaged in most active controversy regarding the low contract rates which had been quoted; the doctors, had, at that time, expressed their dissatisfaction most actively. As to the suggestion that insured persons were being treated by panel doctors as private patients, the regulations expressly forbade that, except in two cases—where the insured person deliberately renounced his right to benefit and expressly demanded to be treated as an insured person, or where, being on a doctor's list and not wishing to change, he went to another doctor and asked for a second opinion or advice for which he wished to pay.

The Trade Union Approved Societies.

The case of the National Association of Trade Union Approved Societies was presented by Mr. Canter, President of the Association. Mr. Canter said the Association had one and a half million members and represented nearly every trade-union. The Association regretted that the Terms of Reference of the Court did not refer to the amendment or extension of the medical service under the insurance scheme; the trade-unions had pressed for a wider service, to include specialist treatment. The view of his Association was that for the medical treatment which was required under the new regulations the doctor would be adequately remunerated by a fee of 7*s*. 3*d*. Although the time at their disposal had been limited, the Association had collected figures from 1300 doctors practising in 250 different towns and areas; and these figures showed that in many cases the doctors did not charge their private patients more than 3*s*. 6*d*. for a visit and 2*s*. 6*d*. for a surgery attendance. This fee gave about 10*s*. for 3·5 services and a deduction of 7½ per cent. for bad debts brought the figure to 9*s*. 3*d*. A deduction for the cost of medicines must then be made. Their figures showed that in 2·8 of the 3·5 services medicines were supplied and the statistics of the South-Eastern District Pricing Bureau showed the average cost of prescriptions to be 8·7*d*., or 2*s*. for the 2·8 prescriptions. The 10*s*. of private practice was thus equivalent to 7*s*. 3*d*. for 3·5 insurance services. He believed that the treatment given to private patients at the fees quoted was as good as, and sometimes better than, the treatment given to insured persons. A customary contract rate for dependents was 1*s*. 8*d*. a month and this covered, on the average, the wife and two children under 16. Allowing the 2*s*. deduction for medicines, this represented a yearly fee of 4*s*. 8*d*. a head. His Association contended that unless and until there were very considerable extensions and

improvements in the medical service provided to insured persons, the medical profession had no claim for a higher fee than he had proposed. They did not agree that the fee paid should be sufficient to attract the higher skilled practitioner to undertake health insurance work unless the insured population were guaranteed this higher skill; in their opinion this could not be expected from the average practitioner who undertook insurance work. They contended that in order to secure this higher skill some alteration in the flat rate method of payment was necessary, or the flat rate should be supplemented by special payments to secure the skill of the better qualified practitioner.

In reply to questions by Dr. Brackenbury witness agreed that doctors had, on the whole, acted considerately to poor persons. The leaders of the medical profession might desire to give a full and adequate service, but he doubted whether the profession as a whole was in a position to give it. The figure of 5 services per person per year had been accepted from the Ministry's case, and had not been verified by independent investigation. He admitted that the private fees quoted did not include certain services within the insurance agreement; and that the Drug Fund supplied insured persons with drugs and appliances for which the doctor would make an extra charge to his private patients.

In reply to Dr. Ward witness admitted that the 8s. 6d. and 3s. 6d. quoted for private practice was not necessarily the maximum fee which a doctor charged.

Mr. Corbey, Secretary of the Association, in supporting Mr. Canter's evidence, said that for the purpose of compiling the figures on which the Association's case was based he had personally visited many districts, interviewed many people, and inspected many of the actual doctors' bills.

Certification Complaints.

Mr. W. Rigby gave evidence on behalf of the Catholic Friendly Societies and Catholic Approved Societies Associations. He said that the approved societies which he represented were not satisfied with the action of panel doctors with regard to certification. A looseness of certification was current which lowered the whole tone of medical benefit and seriously damaged the funds of approved societies. He thought that irregular certification had in many instances tended to put into the background the primary need of curing the insured person. They were now insisting on a closer medical examination, and were obtaining the assistance of the regional medical officers. Witness quoted instances where the R.M.O. had disagreed with a high percentage of certain doctors' certificates.

Dr. Brackenbury inquired what reduction in the capitation fee would, in the witness's opinion tend to produce more careful certification.

Continuing, the witness said that many insured persons received treatment in hospitals. The figures from 15 areas showed that out of 10,000 members 2159 were on the funds receiving 18,500 weeks' benefit, of which 2500 weeks—nearly 1 in 7—represented hospital treatment.

The Chairman inquired whether it was not often difficult for the doctor to act fairly as between the approved society and the insured person on questions of certification. Witness admitted that it was so, and said that in the north of England many doctors had told him that it was very difficult to refuse to issue certificates at the request of insured persons without endangering their practice.

The Seamen's National Insurance Society.

Mr. Godfrey said that the Seamen's National Insurance Society was the only society which dealt directly with the doctor for insurance purposes. The object of the Society was to provide medical treatment to seamen while they were on shore, and this was done by means of the fee system. The scale of fees drawn up when the Insurance Act came into operation had been increased by 20 per cent. in 1919 and by 50 per cent. in 1920, a reduction of 10 per cent. being made in 1922, a further reduction was now contemplated, but it was proposed to await the decision of the Court before deciding its extent. The present scale was 3s. 6d. for a visit and two days' medicine and 2s. 1d. for a surgery attendance and medicine, with special payments for night visits, mileage, and special services.

Throughout the 11 years during which the Society had been established they had nothing but praise for the way in which doctors had given treatment; they had attended the seamen in a most sympathetic manner.

Mr. Chambers, on behalf of the National Sailors' and Firemen's Union, said that during a period of three weeks, 1600 members had sent in certificates of incapacity, and of these 306 were hospital certificates. He suggested that, as the capitation fee would be paid in respect of all insured persons, account should be taken of the large number who did not trouble the panel doctor while in hospital.

The Experience of Welsh Societies.

Mr. Rowland H. Jones, secretary of the Denbighshire Association of Approved Societies, said that in his experience the medical service since 1912 had improved each year in South Wales, but it was not yet satisfactory. Many doctors did not give equal treatment to their insurance and private patients. Certificates were often loosely given, particularly at the beginning and at the end of an illness. In some instances 50 per cent. of the cases referred to regional medical officers showed incorrect certification. He thought that more might be done to relieve the insured person from having to walk a long distance, sometimes ten miles to the surgery; there might be a weekly examination at a suitable village centre. His experience on the Medical Service Subcommittee for Denbighshire showed that the medical members acted very fairly; the decisions of the Subcommittee had always been unanimous. He had met many cases where the insured person had refused to put in complaints. As to the amount of the capitation fee, he thought that 7s. 6d. was sufficient, although he would not object to 8s.; this would represent an increase of 100 per cent. on the normal pre-insurance contract figure of 4s. For doctors in rural areas an additional payment should be made for mileage and, in his opinion, the existing mileage allowance should be increased.

MONDAY, JAN. 21ST.

The case of the Emergency Committee of the Provisional General Council of Approved Societies was presented under three headings: (1) Medical contracts, (2) certification, (3) medical benefit regulations.

Pre-Insurance Contract Practice.

Mr. William Wood (Secretary of the Scottish Rural Workers Approved Society) contended that practically no service had been rendered to insured persons who were not on any practitioner's panel and that the distribution amongst the panel doctors in each area of the capitation fees of these persons was practically a free gift to the doctors, which should be taken into account in fixing any general capitation fee. The figure of 3·5 as the average number of attendances per insured person per annum was arrived at from records kept by doctors themselves, and was regarded by the Society as unreliable, because in many cases the formal granting of a certificate of incapacity was recorded as an attendance.

The Chairman excluded a recommendation for a graduated scale of remuneration as being outside the scope of the inquiry.

Mr. S. L. Duff (Permanent Secretary, Ancient Order of Foresters) gave evidence on Part I. of the Committee's case. Prior to 1913, he said, most of the contracts between friendly societies and the medical profession provided for a capitation fee of 4s. including medicines. In certain respects, it was true, the present-day insurance service differed from the older club practice. Under the pre-insurance contract

system, certification was simpler and such record keeping as was required was of an elementary character; there was also a process of health selection, but this had been greatly exaggerated; sometimes men up to the ages of 21, 25, or 30 were admitted without medical examination. Apart from these factors the medical benefit was substantially the same as under the present insurance agreement, and he thought that the sudden rise in the doctors' remuneration from 4*s.* with medicine to 7*s.* 3*d.* without medicine was entirely unjustified. An initial mistake had, he believed, been made in fixing the doctors' remuneration when medical benefit under the Insurance Act first became operative, and this error had continued in each subsequent settlement. It was fortunate for the doctors that, at the time of the 1912 settlement, the fortunes of the Chancellor of the Exchequer were bound up with the success of the Insurance Act. Almost on the eve of the commencement of medical benefit the British Medical Association—who were great organisers—had advised the doctors to refuse service, and it was only as a result of this that the high fee of 7*s.* 3*d.* had been paid. As regards the 1920 arbitration, witness suggested that it would be difficult for the arbitrators entirely to dismiss the original figure of 7*s.* 3*d.* from their minds, and so the original error had been continued. Had the award been postponed for even two months he thought a lower fee would have been fixed, as by then the nation had recovered the economic perspective which was lost in the years after the war. His committee maintained that even if the medical service offered to insured persons was perfect within the compass of the regulations, the capitation fees fixed in 1913, 1920, and 1922 were excessive. The present Court had an opportunity to apply a corrective to the initial error.

Mr. W. Marlowe, Secretary to the National Conference of Friendly Societies, said that his Conference represented 69 district societies with 7,420,000 voluntary members. He claimed that the actual remuneration received by the doctors for their attendance on friendly society members in pre-insurance days provided a clean jumping-off ground for determining the capitation fee for insurance practice. In 1898 the General Medical Council had convened a Conference with representatives of friendly societies and nothing beyond a capitation fee of 4*s.* including medicines had even been suggested. In 1908 the British Medical Association had convened a Conference, and there had been no expression of dissatisfaction with the contract terms of the friendly societies. That being so, he did not see why the fee should jump to 7*s.* immediately the Insurance Act came into operation. Under the old friendly society régime the relations between the doctor and the patients were sound and good and the doctors had been kind and generous; the relations with the societies, too, had been pleasant, and the doctors had been anxious to undertake the work. He contended that the 4*s.* was the right figure from which to start, and that allowing for the altered conditions of living, 7*s.* 3*d.* was all that should be paid at the present time, not a penny of this to come from the funds of the approved societies. The approved societies wished to be friends with the doctors; but he thought that the doctors had a low opinion of the friendly societies.

Dr. Cox said that he could assure Mr. Marlowe that the doctors had no such low opinion of the societies as he suggested, but it was sometimes difficult for them when the societies themselves had such a low opinion of what the doctor's work was worth. If the doctors were completely satisfied with the pre-insurance friendly society practice, why had the profession refused to work the National Insurance Act under the ægis of the friendly societies? Mr. Marlowe, having replied that it was because the profession desired to obtain complete control, Dr. Cox quoted the opinion expressed to the profession by Mr. Lloyd George in 1911 that in this respect they had a legitimate grievance. In reply to further questions by Dr. Cox, Mr. Marlowe said that the only certificates required in friendly society practice was a declaring on and declaring off certificate; no records had to be kept by the doctor, and members were usually admitted only after medical examination.

The Chairman indicated that the Court would not give undue weight to what happened before 1911.

Mr. G. L. Lingstrom, Past Grand Master of the Manchester Unity of Oddfellows, said that the original capitation fee of 7*s.* 3*d.* was obtained because the profession took undue advantage of the needs of the community, by threatening to refuse service under the Insurance Act. In his opinion 7*s.* 3*d.*, which represented an increase of 3*s.* 3*d.* on the old friendly society rate of 4*s.*, was adequate; the doctors should be paid an economic rate, based on the rate which was customary before they received assistance from the State. The old friendly society service was satisfactory to the members, and the relationship between the society and the doctors had been good; yet as soon as the Insurance Act came into operation the doctors raised their fee from 4*s.* to 8*s.* 8*d.* for private contract work. The service available to the insured person might, perhaps, in some respects, be better than the earlier club service—e.g., as regards expensive drugs and appliances, but as regards the services given by the doctor it was not better. In reply to the Chairman, witness said that the figures for 53 branches showed that the fee paid to the doctor in respect of non-insured members varied from 8*s.* to 20*s.*, with an average of 12*s.* 6*d.*; the figures for 23 medical institutes showed fees ranging from 6*s.* to 16*s.*, with an average of about 8*s.* 6*d.* All these rates were influenced by the original excessive insurance fee of 7*s.* 3*d.*

Certification.

Mr. J. P. Lewis, Secretary of the Hearts of Oak Benefit Society, said that the number of certification cases which came before insurance committees offered no criterion of the extent of irregularities. Although only 1339 cases had been dealt with since 1920, the pitiable point was that 60 per cent. had gone against the doctor. Sickness benefit became payable only at the beginning of 1913, yet in August of that year a departmental committee had to be appointed which had resulted in the establishment of regional medical officers. Information recently collected by societies representing more than one-half of the insured population of Great Britain, showed that out of a total of 56,107 cases referred to R.M.O.'s, during the first six months of 1923 14·5 per cent. cases were fit to work, 44·8 per cent. cases were unfit, and in 40·7 per cent. cases the insured person failed to attend. Most of those who failed to attend would have been declared fit since the date of citation. Out of one group of 41,836 cases referred, 18,335 failed to attend and investigation showed that 16,871 of these had declared off prior to the date fixed for examination, only 1464 being actual failures to attend. Of 15,201 cases found incapable of work or declared off, 588 were those of members who had been furnished with monthly certificates of incapacity.

In reply to the Chairman, witness said that he appreciated that certification as to incapacity was often a difficult matter for the doctor. The appointment of regional medical officers had worked some improvement: whether it would result in further improvement depended on whether the doctors took to heart the lessons to be learned from the cases referred to R.M.O.'s.

Mr. E. F. Spurgeon, National Conference of Industrial Approved Societies, said the funds of approved societies were the property of the members, and references to R.M.O.'s were, therefore, solely in the members' interest. Applying their experience to the figures of the Ministry of Health, out of 107,242 references to R.M.O.'s it might be assumed that 53 per cent. had been found fit to work. The approved societies were anxious to coöperate with the doctors; and they did, in fact, receive coöperation from a large number of insurance doctors. He considered that the certificate should enable the society to satisfy itself from the health point of view that the member was

tually incapable of work. The societies did not fer cases to the R.M.O. until the member had been for four weeks and then only on the recommenation of one of their medical officers; thus six or seven eeks would usually elapse between the beginning of ie illness and the R.M.O.'s examination. On many rtificates the cause of incapacity was insufficiently ated; there was a tendency to certify sickness rather an a specific disease. He thought that much of the ose certification was due to careless and cursory camination of the patient; thereby adequate treatent might not be provided, and the patient's covery might be postponed. He hoped that the rofession would realise that the approved societies sired to extend coöperation to every doctor on the anel.

The Range of Service.

Mr. H. Lesser dealt with Part III. of the Committee's se. He denied that greater obligations and sponsibilities had been imposed on the doctors since 913. Section 15 of the National Insurance Act, 1911, rovided that the arrangements to be made by surance committees should be such as to secure dequate medical attendance and treatment from surance practitioners; that must mean treatment dequate to the general purposes of the insurance heme; and from that standpoint the doctors were equired to do no more in 1924 than in 1913. The ew definition of general practitioner treatment did ot extend the range of service; it altered the wording ot the substance. The provision as to surgery ccommodation and practice arrangements were ecessary only to enable action to be taken in exceptional cases, but did not increase the obligations of the octor. The doctors had, moreover, always accepted he principle of collective responsibility, and had eceived remuneration for this; thus, in the London rea, the 11*s.* capitation rate had actually produced 1*s.* 6·94*d.*, while the 9*s.* 6*d.* fee had given 9*s.* 10·2*d.* nd 9*s.* 7*d.* in 1922 and 1923 respectively. As regards heir certification obligations the doctors seemed to uggest that their only duty was to their patient, but his was an entire misconception; in the administration of benefits under the Insurance Acts the loctors and the approved societies were correlated. The supposed additions to the doctor's obligations vere all included in the general requirement of an dequate service, and while this overriding provision f the Act remained, he thought that the Court should lismiss the doctors' claim.

The Societies' Case Concluded.

Sir Thomas Neill concluded the case on behalf of the pproved societies. He said that if one considered the ctual details of the work of a large approved ociety involving, for example, 69,000 claims a year, vith special reports in 25,000 cases and the provision f treatment for 6000 tuberculous members, it would e realised that those associated with approved ocieties were actuated only by motives of national ervice. They desired to do all that they could to lift p the service, and for that purpose they wished to e able to talk over matters with the doctors. They lid not want to feel that the doctors were so high and nighty that they could not enter into mutual discussions. The "hands off" attitude adopted by the rofession with regard to a service towards which the State contributed was, in his view, most undemocratic.

Further evidence might have been submitted by his ide regarding the time rate equivalent. It was not lear that the records on which the Ministry's figure f 3·5 services per insured person was based excluded ttendances in respect of confinements, neither did hey know to what extent the correctness of the ntries on the records had been checked. There were, n an average, 3500 insured persons in hospital; the doctor was not at risk at all as regards these. There were, also, many persons who had not selected a doctor; assuming the number to be 10 per cent., it represented £750,000 even at the 7*s.* 3*d.* capitation fee. He hoped that the Court would, in the interests of all parties, be economical in their decision: they had arrived at the stage when inflated payment for services of this kind could not be maintained.

Mr. Abbott informed the Court that the annual report of the Minister of Health showed that the number of insured persons who had not selected a doctor was only 5·2 per cent.

Dr. Ward, on behalf of the Medical Practitioners' Union, in the course of a further statement expressed the view that the figures on which the Ministry's calculations were based were not those of an average practice; and he doubted whether the figures had been taken from a proper proportion of town and country practices. The average salaries of regional medical officers had shown progressive increases from 1920 to 1922, yet the insurance doctor's remuneration was to be decreased. He thought that the present certification rules exceeded what was necessary. The obligations of insurance practitioners were bound to increase and therefore any capitation fee decided on should not be reduced if recommended for a term of years.

The Reply to the Societies.

Dr. Brackenbury replied to the case of the approved societies. He said that he did not propose on that occasion to deal with the many detailed points which had been raised. He confessed a difficulty in seeing the relevance of much of the evidence. The approved societies contended that the doctors should receive less because the service was not as complete as was desirable. He sympathised with that view; the profession would like to see a service which would include everything which the insured person could need; but it was surely begging the question to say that the doctor's remuneration should be reduced because there was not that full service; the question was the value of the service which was in fact being given. The profession did not complain of the increase in their responsibilities since 1913; they had themselves suggested many of them, but they did claim that in certain important respects—e.g., the provision of emergency treatment and the administration of anæsthetics at specialist operations, additional duties had been laid upon them, and that the value of those services must be assessed. It was said that the fee should be reduced because the area of the doctor's responsibility was limited by the number of insured persons who had not selected a doctor. That argument showed an amazing ignorance of the principles of insurance. Because under an insurance scheme there were liabilities which did not mature, it was surely wrong to suggest that those liabilities should be borne for nothing. It was entirely wrong to assume that all insured persons treated in hospitals were cases which the insurance practitioner ought to treat; they were mostly cases falling outside the insurance agreement. In smaller towns, moreover, the hospitals were staffed by the local general practitioners. It was said that many of the doctor's duties, such as the writing of certificates, were trivial, yet the societies attached great importance to certification and said that it should be carried out with great care. Dealing with the suggestion that the fee should be reduced because the service rendered by the doctors was not a good one, Dr. Brackenbury was proceeding to quote the evidence of the Ministry and of the insurance committees, when the Chairman observed that the Court would not regard any defect in the service except in relation to certification upon which specific allegations had been made.

On the question of certification, Dr. Brackenbury said that it was quite wrong to assume that there was necessarily incorrect certification in all cases where insured persons were declared off between the date of citation and the day appointed for examination by the R.M.O. It was only natural that the cases referred by societies should be mainly those where the patient was getting near the end of an illness and would therefore, in any event, have been certified fit for work before the date of the R.M.O.'s examination. It was often a matter of real difficulty to say definitely that a patient was unfit for work one day and fit on the next. The medical profession attached

considerable importance to certification; to sign a false certificate was a very serious thing for a medical man; neither did they wish to palliate lax certification. They recognised their duty in this respect, but it was an oppressive duty and had been placed on them over and above their duties to their patients; there was nothing comparable to it in private practice; and it must be taken into account in deciding the amount of capitation fee.

As regards the pre-insurance club practices, he accepted the evidence of the insurance committees that the insurance scheme offered a better service. He could not admit that the contract rate of 4*s*. was adequate, but even accepting that, it was to be noted that a customary service rate in those days was 1·25 services per member per year. Assuming a present day service rate of 3·77, even the 4*s*. rate would be equivalent to 12*s*. in insurance practice, less 1*s*. for drugs, but with an addition for certification, records, and increased range of service.

In conclusion, Dr. Brackenbury said that he could not believe that the approved societies seriously suggested that a reduction in the capitation fee would really improve the service available to insured persons, neither did he think the societies would desire that the pay from insurance work should be so low that the doctor would devote most of his time and interest to his private practice. The profession wholeheartedly desired that the insured person should receive as complete a service as is given to private patients, but to secure that it was necessary that the capitation fee should be comparable to the income derived from private practice.

In concluding the sittings of the Court the Chairman thanked all the parties for the excellent way in which they had presented their evidence. He hoped that the Court would be able to issue an early report.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The Projected Insurance Scheme and the Medical Profession.

THE Chambre des Deputés has under discussion a new proposal with regard to an insurance scheme, a subject which is of topical interest to the English medical world. Under the proposed scheme insurance will be of two kinds, compulsory and voluntary. The first category includes all those persons whose income is less than 10,000 francs per annum, allowing another 2000 francs for each dependent child under 16. A levy of 10 per cent. is made on the basis of the income, contributed partly by the employer and partly by the employee, and in return the insured person may claim medical treatment and drugs for himself, his wife (if not a separate wage-earner), and his children. A daily allowance amounting to half the regular salary is made in case of illness, and for disablement a pension of 500 to 3000 francs, according to the scale of the contributions, is allowed. A further allowance is made to wives during the three months preceding and the three months following childbirth, while obstetric treatment is provided free. The number of wage-earners affected by the compulsory insurance is estimated at 12,000,000, including wives and children. In addition thereto farmers, artisans, small employers, and small merchants are eligible, provided that they are not more than 30 years of age and free from any chronic malady. It has been decided to place the administration of the funds in the hands of mutual benefit societies. Insurance societies are authorised to make contracts for medical service with the doctors, on condition that the following three principles are maintained: (1) free choice of doctor by the insured party; (2) collective contract; (3) adoption of part-payment coupons. Free choice of doctor is, however, limited to such medical men as have signed a collective contract with a society, and as the society will naturally endeavour to contract at the lowest possible capitation figure, the contract doctor will be obliged to enrol a clientele of unwieldy proportions. The part-payment coupon is designed to circumvent abuses of the society's funds by laying a small charge directly on the insured person for all medical treatment he receives, but it is doubtful if the object desired will be achieved. The main objection to the working of the law is that the interests of the insurance societies will be constantly opposed to the doctors' professional interests; the detection of malingering will be of greater moment from the society's point of view than careful ministration to the sick. In view of the unanimous protests of the organised medical profession the Bill has been submitted for revision, but will shortly be laid before the Chambre, which will doubtless make it a plank in the forthcoming election platform. French medical opinion is not concerned with the political aspect of the question. Its sole object is to consider the insurance scheme from the point of view of the medical profession in maintaining a high standard of technique and efficiency.

Instruction in the Technique of Sanitation.

As provision for practical training in sanitation has hitherto been lacking in France, the Under Secretary of State for Technical Education has added to the National Conservatory of Arts and Crafts an Institute of Sanitary Technique, open to all whose studies or whose profession demand a scientific knowledge of sanitation. Duly matriculated pupils may obtain a diploma in sanitary technique on satisfying a board of examiners. Non-matriculated pupils who do not wish to qualify may attend the lecture courses on application to the Director of the Conservatory. The training will be free, and the complete course will not exceed three months, in order to allow candidates who do not live in Paris to complete their studies in the shortest possible time. The course will include theoretical lectures, practical demonstrations, and visits which will occupy the whole of each day. At the opening of this institute, which took place recently, the director, Mr. F. Heim, outlined the purpose of the work. "The object of the institute," he said, "is to give engineers, architects, builders, and all others who are concerned in matters of hygiene an opportunity to acquire knowledge which will enable them to embody sound hygienic principles in their constructive work, and thus further the material welfare of the community."

Hygienic Measures following the Floods of Paris.

During the recent floods the Parisiens suffered more from apprehension than from the realisation of their fears. The waters of the Seine remained at 25 cm. below the flood level of 1910, but these 25 cm. spared Paris the disasters of 14 years ago. From the medical point of view, the unfortunate happenings which were recorded in THE LANCET of Feb. 5th, 1910, have not been repeated on this occasion. Only a very circumscribed area of Paris, in the seventh arrondissement, was deprived of electricity, but no damage was caused either to hospitals or to hospital installations. Refugees who were forced to leave their dwellings were allocated to empty military buildings situated on the fortifications. The Ministry of Hygiene instituted a daily medical visit to each of these buildings, and provided a staff of nurses to care for the sick, the convalescent, the mothers, and the children. The population of Paris was warned, by means of a circular, not to drink water from public fountains or wells unless it had been boiled or otherwise purified. Other sanitary provisions were as follows. Wells and cisterns must be cleaned and disinfected (500 g. of calcium or potassium permanganate per cubic metre of water to be disinfected). Conduits must be examined, and where polluted by infiltration they must be put in order and cleaned. The consumption of uncooked vegetables has been temporarily proscribed; all foodstuffs which might

have been subjected to pollution must be cooked. Houses and outhouses are to be cleared of mud and filth, which must be deposited at a safe distance from any drinking water-supply. Plaster and lime, added to the mud, is recommended as a convenient drying method. Disinfection is carried out by carefully mixing about 5 kg. of quicklime with every cubic metre of mud. The floors of dwellings must be disinfected either by whitewash in the case of earth floors, or by thorough washing with an antiseptic solution (eau de javel, cresyl, warm lye, &c.) when the flooring is of wood. The same precautions must be taken with cellars and basements. Soiled mattresses must be burned and other bedding washed and disinfected. Schools, workshops, factories, and shops may not be reoccupied until such measures have been carried out. With these precautions no sudden epidemic or aggravation of sanitary conditions have been provoked by the floods.

Public Health Services.

SCHOOL-CHILDREN ON THE ISLAND OF LEWIS.

THAT conditions on the Island of Lewis are incredibly hard at the moment is borne out in the reports for 1922 and 1923 of the school medical officer, Dr. Agatha E. Miller. These islanders are always faced with the primitive struggle of wresting a living from the natural resources of their surroundings; the last three years have been lean ones, and there is now a strenuous fight for existence. Children's weight here fluctuates according to whether the harvest be good or bad, and there is an annual "spurt" in weight throughout the island after harvest. A good harvest in 1920 meant an increased average weight in the summer of 1921. A poor harvest in 1921 resulted in a decreased average in 1922. In 1922 the harvest was better again, and one would have expected improved weights in 1923. In this we are disappointed. The fishing and tweed failures, with the consequent loss of employment, have told against the children. "The outlook," writes Dr. Miller, "for the coming school year, with the wet season, the failure of the harvest, and the condition of the peat, is black indeed."

On entering upon school life the physique of these island children, who come of a noble, well-built race, gradually deteriorates. They enter school well above the normal in every way; indeed, in previous years the entrants have been very much above the average in weight, but as school years pass the children below the average increase in number. In districts specially dependent on the harvest the deterioration is greatest. Feeding experiments during the last three years in one large school demonstrated that this deterioration was dependent on want of food alone. The result of the provision of merely a cup of cocoa or soup at midday was that of 61 infants of 5 and 6 years of age not one was below 40 lb. in weight. With the stoppage of this midday soup or cocoa and failure of the harvest 13 per cent. fell below. Similarly, of 28 children of 12 years only 2 were under 70 lb. in weight and 50 per cent. fell below. The weight averages of boys of 5 fell from 45·56 lb. to 41·40 lb., and for girls from 47·38 lb. to 44·31 lb. Boys of 12 fell from 76·68 to 73·54, and girls from 79·13 lb. to 71·62 lb. In 1922, owing to the lack of funds and the inability of the parents to pay the necessary penny, the provision of a cup of hot cocoa at midday was stopped, and so grave is the present outlook that teachers all over the island are taking steps to raise the necessary funds for midday soup or cocoa. The distress is so general that it is feared that unless relief works of some kind are started all over the district within the next week or two the children will have to be fed from outside sources. The country children almost invariably belong to crofter fishermen, who welcome whatever casual labour they can get. Unfortunately there has been little or no work available for the last two years. The children of men who did not come back from the late war are conspicuous by their good clothing and superior nutrition. The rural population here differs from that in southern areas inasmuch as, having a hereditary right to the soil it is stationary, and fundamentally the race is good, as is demonstrated by the teeth. Two-thirds of the children examined had perfectly sound teeth. The majority of defective teeth was accounted for by the town children. No cases of rickets of long bones has been met with in Lewis for the last three years. Individual children removed to a home or even fed with the addition of oil at their own homes can easily put on a stone in weight in a month. The children, too, are clean. In the country districts vermin are few in number, though in the town this infection presents a serious problem. In Lewis altogether a wonderfully high standard of cleanliness is maintained. No dirty heads were noticed. The hair is usually washed weekly. All the water has to be carried from the well, as in country districts; even in the towns a number of houses have no water and few indeed have baths.

The result of an investigation into the social conditions in the black and white houses in Lewis is given in Dr. Miller's report. Evidently the feeding of these islanders is an urgent undertaking which should not be delayed.

"Audi alteram partem."

THE PROMOTION OF MEDICAL HYDROLOGY.

To the Editor of THE LANCET.

SIR,—We desire your support in bringing before the profession the need for systematic teaching of medical hydrology, by which term is to be understood the science of treatment by waters internally and by heat, cold, and other agencies in baths and external applications. The General Medical Council have now definitely recommended that instruction in physical treatment should be included in the teaching of therapeutics, and we believe that the science of medical hydrology must be the foundation of such instruction. A joint committee of the International Society of Medical Hydrology and the Section of Balneology of the Royal Society of Medicine has been formed to promote the teaching of medical hydrology in England, and has already established a course of lectures on the subject under the London University Extension Board. It has further drawn up a statement and presented it to the Ministry of Health, pointing out how far we in England have fallen behind continental countries in this direction and how this state of things may be remedied.

Through the medium of your columns we now seek to inform the medical profession generally of our aims, which may be thus summarised:—

1. *Research.* The establishment and endowment of a central institute and laboratory for encouraging and co-ordinating systematic research into the physical and chemical properties and the pharmacological action of the British medicinal waters, and of the action and use of baths.

2. *Teaching.* Post-graduate; courses in London and at other universities. Students; inclusion of systematic lectures in the courses on therapeutics. Practical; study tours to British spas.

3. A complete *survey* of British medicinal waters.

4. Official *authorisation* of such waters. (Compare the official authorisation of drugs in the British Pharmacopœia.)

5. For the purpose of carrying out these objects, the establishment of a permanent *advisory committee* analogous to the French "Commission des Eaux Minérales."

Of the total working time lost by the population through illness, a very large proportion is due to chronic disease of the rheumatic type, which are more effectively treated by hydrological measures than in any other way. That this is already recognised in some quarters is shown by the voluntary contributions made to our great mineral water hospitals by

working-class organisations and other bodies responsible for the health of the poor. But it is not only the poor and the so-called working-class that need to be considered, for, as authorities have already pointed out, a great field of usefulness exists for such treatment at the health resorts in the early and preventive treatment of many diseases which seem to be peculiar to the strenuous life of to-day and which may perhaps be summed up as premature breakdowns. These conditions seem to affect particularly the brain workers of the nation, and their consequences, though less obvious, are perhaps of even greater importance than those previously referred to.

The importance of research and instruction in the treatment of these conditions, among others, needs no argument, and it is to effect this object that we are directing our efforts.

On behalf of the Committee,

We are, Sir, yours faithfully,

C. W. BUCKLEY,
W. EDGECOMBE,
R. FORTESCUE FOX,
R. G. GORDON.

36, Devonshire-place, W.,
Jan. 17th, 1924.

THE AURICULAR BEAT.

To the Editor of THE LANCET.

SIR,—Dr. G. Arbour Stephens raises an interesting point in his letter in your last issue as to the production of the sound, which we called the "auricular beat," by which we meant an exterior manifestation of the auricular contraction. Though there were 5 oz. of effusion in this case, in another, a boy of 14 whose ventricular rate for 24 hours before his death varied from 6–12 per minute, the auricular contractions were also well heard and there was no excess of fluid in the pericardium. In the case to which Dr. Stephens refers, the pericardial effusion was probably a terminal event; whereas the auricular beat, which was loudest at the earlier stage of the disease, had ceased to be evident for some weeks before death. The sounds corresponded absolutely to the auricular and ventricular contractions as shown by the cardiograph. Putting aside the question as to whether muscular action may cause vibrations audible as sound, one would consider that the sound manifesting the auricular contraction is produced in the same way as the third heart sound, and is due to a forcible contraction of the auricle driving the blood into the passive ventricle, thereby causing currents which close the auriculo-ventricular valve with varying degrees of force. It is also possible that if this closure is pronounced the shock might even be transmitted to the arteries.—I am, Sir, yours faithfully,

Wimpole-street, W., Jan. 21st. A. J. SCOTT PINCHIN.

EARLY HUMAN EMBRYOS.

To the Editor of THE LANCET.

SIR,—It would be kind of you to make known our pressing need for early human embryological material. An investigation is being made of the ductless glands and other organs of the human fœtus by members of the staff of the anatomical and histological departments of the London (R.F.H.) School of Medicine for Women. Up to the present the greater number of fœtuses received from our hospital and other sources are aged from 6 months upwards, the younger embryos being scarce. We should be grateful to any reader who could send us such material. The following suggestions for sending it are offered.

1. The fresh material should be fixed for at least one day before sending in 5 per cent. formalin made up with tap-water if normal saline is not available.

2. In complete abortions the sac should be carefully snipped to allow free entry of the fixing fluid.

3. Small embryos travel best in fixing fluid: the receptacle should also contain sufficient cotton-wool to prevent damage by shaking.

4. Larger embryos, after fixing for at least two days in 5 per cent. formalin, may be packed up with cotton-wool soaked in the formalin, and the whole wrapped in oil-silk or like material.

5. Material in central London districts could be called for on receipt of a telephone message to Dr. Lucas Keene at the London School of Medicine for Women between 9 A.M. and 5 P.M. any day but Saturdays and Sundays.

It is scarcely necessary to say how extremely important it is to obtain material as fresh as possible. A short history of the case, including age of mother, notes of previous pregnancies, also whether syphilitic or no, adds greatly to the value of the specimen. We shall be only too glad to report to the sender findings of any interest should he so desire.

We are, Sir, yours faithfully,

M. F. LUCAS KEENE.
E. E. HEWER.

IMMUNISATION AGAINST DIPHTHERIA.

To the Editor of THE LANCET.

SIR,—In a paper read before a joint meeting of the Society of Medical Officers of Health and the Royal Sanitary Institute, held at Blackburn in the spring of 1922, dealing with my experience of the Schick test and toxin-antitoxin immunisation, I contended that the question was primarily one which concerned the public health authorities. The leading article in THE LANCET of Jan. 19th, prompts me to urge this view once more. Sufficient work has been done by Park, Zingher, and others to show that the Schick test is a reliable indicator of susceptibility to diphtheria, and also that toxin-antitoxin immunisation confers protection which lasts for years, possibly for life; at any rate certainly for that age-period when the majority of children are Schick-positive.

Public health authorities, through their child welfare and school medical officers, come into daily contact with children at the most susceptible age-period, and also under conditions which favour accurate tests and careful observation. If, as the result of judicious propaganda and enlightenment of their controlling public bodies, medical officers of health were to make practical use of this recent discovery in preventive medicine, to them, in no small measure, would be due the credit of having greatly minimised and perhaps ultimately abolished a universal and dangerous disease.—I am, Sir, yours faithfully,

T. E. DICKINSON.

Bedford-square, W.C., Jan. 21st, 1924.

MALARIA CLINICS IN RUSSIA.

To the Editor of THE LANCET.

SIR,—The Malaria Clinic in Buzuluk was the first opened by the Quakers in the famine area, and is now the centre of a number of similar clinics scattered over a wide country district. In the last week of October, 1922, I reached Buzuluk, but had to wait a fortnight for the clinical laboratory outfit which I had bought in London. Dr. Melville Mackenzie, who was then the chief medical officer of the Friends' Mission, suggested [1] that in the meantime I should make examinations for malaria of the blood of a few families connected with the Mission. There had been a very severe epidemic of tropical malaria during the summer and the death-rate was very high. The news spread through Buzuluk that the Quakers were going to treat malaria, and within the first week the medical office was besieged with hundreds of would-be patients. We had a certain amount of quinine—a gift from the British Government—and it seemed impossible to refuse them, so the following rules were drawn up by Dr. Mackenzie:

1. Only those patients to be treated in whose blood malaria parasites could be demonstrated.

2. No quinine to be given to take at home, but patients to attend as required at the Mission dispensary and take their dose under supervision.

3. The patient to agree to take the full course of quinine.

Without these rules some patients would have sold quinine handed out to them, and many more would

[1] See M. D. Mackenzie: Malaria in South-East Russia, THE LANCET, Dec. 8th, 1923, p. 1225.

have shared it with friends, or have put half of it aside for the dreaded time when probably there will be no Quakers and consequently no quinine. The numbers have gone steadily up from an average of 50 new patients daily to 200 and more in Buzuluk alone. No certain figures are obtainable, but from general observations 80 per cent. may be taken as a low estimate of the number of the population affected by the disease. People come to the clinic from as far away as 50 miles, arriving behind horses, cows, or camels, their various equipages filling the street for a hundred yards. The quick results of quinine treatment astonish even those of us who have long been accustomed to malaria work in tropical countries. Patients seldom have an attack of malaria after commencing treatment.

It has never yet been possible to receive every patient who applies, as the number has to be restricted by the amount of quinine in hand for the month. We receive quinine now almost entirely from America in very large quantities, but even so every clinic (of which there are now several which have been opened one by one in various parts of the country) has an allowance much below what it could use. The patients are extremely grateful, especially those who have to work in the fields, as daily attacks of malaria prevent many from getting on with the ploughing in the spring, and this means starvation for their families in the following winter and in the aggregate a great setback to the slowly returning prosperity of the Ooyezd. If people could only see the street outside the clinic on any market day they would understand why it is hard to choose which patients to turn away. It is no uncommon thing to find an unconscious man on the pavement or road, no one taking much notice of him or attempting to move him to a safe place, for people are used to this by now and so many of them are sick themselves.

Those who are turned away from the clinic have absolutely nowhere else to go for help, and what we want to do is to make it possible to receive all who come. I appeal, therefore, to any who are interested to make gifts of quinine so that we need not turn away those who need our help.

I am, Sir, yours faithfully,

ETHEL M. CHRISTIE,
Supervisor of Malaria Clinic, Buzuluk; formerly Assistant Pathologist, Royal Westminster Ophthalmic Hospital.

Jan. 10th, 1924.

*** We understand that gifts of money or quinine will be gratefully received by the Friends' Council for International Service, Devonshire House, 136, Bishopsgate, London, E.C. 2.

PROF. WHARTON JONES AND THE LATE SIR JOHN TWEEDY.

To the Editor of THE LANCET.

SIR,—Apropos of the letter in your last issue from the Rev. P. G. Cawley, the following anecdote communicated to me by the late Sir John Tweedy may be of interest to your readers. Sir John Tweedy gave me the facts of the case for publication in my "Lives of the Fellows of the Royal College of Surgeons," and it seems only yesterday—it was in October, 1919—that he told his story with unusual vivacity, his painful breathing momentarily forgotten, and with something perhaps of a return to the spirit of his early journalistic days.

Sir John (then Mr.) Tweedy being present at a staff meeting of THE LANCET was asked whether he had got ready a biographical notice of Mr. Wharton Jones, as the latter had written to University College Hospital to say that he was unable to attend, and it was therefore inferred that he was ill. It was feared that at his age illness might indicate "the last phase." Mr. Tweedy at once called on Wharton Jones to inquire about the state of his health. It was during the week of the great blizzard of January, 1881, when the snow lay heavy in the streets of London for seven days and all traffic was at a standstill. Wharton Jones occupied a house, where he had given rooms to a poor couple, husband and wife, who looked after him in return for their lodging. To Mr. Tweedy's horror, when he entered his old teacher's room, he found him crouched beside a fireless grate, his shoulders hunched up under a mass of shawls and shabby wraps, the picture of destitution. He was gnawing a cold and uninviting piece of beef-steak and a crust of bread, the wretched meal being all, as the woman of the house informed the visitor, that she and her husband could spare from their own scanty food-supply. Wharton Jones, the distinguished man of science, the revered master of Huxley, was dying of starvation or at least of malnutrition. He had not a penny of money, he was ill, his food was such as his visitor saw. Mr. Tweedy took prompt measures and called on Dr. Sidney Ringer, to whom he said: "Do you know that Wharton Jones is dying of starvation?" At once a rescue party was formed. Mrs. Sidney Ringer, with much experience as a nurse and a kind heart, started off forthwith with soup, jelly, and other restoratives. Her husband wrote a cheque for £25. Armed with this, Mr. Tweedy stepped over to Mr. (afterwards Sir) John Erichsen and told the story. Greatly concerned, Erichsen wrote a handsome cheque. Mr. Tweedy paid other calls on leading medical and scientific men, friends, and colleagues of Wharton Jones, and, in a few hours, had collected £140. This sum was paid into the bank by Erichsen in sovereigns so that the beneficiary might not guess to whom he was indebted. His life was saved. About this time Huxley, on whom Mr. Tweedy had called, Erichsen, and another eminent man, Sir Joseph Fayrer, laid the case before Mr. Gladstone, then premier, who said that the Pensions List was made up, but that Wharton Jones should be in the next Civil List. Eventually he received a pension of £100 or more, to which was later added the Tancred Pension granted him at the instance of Sir William Jenner, then President of the Royal College of Physicians.

Wharton Jones never knew who his benefactors were or what Tweedy had done for him. In his retirement at Ventnor, where he was known as a quaint local figure, he managed to save some £600 before his death on Nov. 7th, 1891, ten years after the destitution episode. This money was, I have heard, left to a legal friend, to whose good offices Wharton Jones erroneously believed himself to owe his safety from starvation.—I am, Sir, yours faithfully,

VICTOR G. PLARR,
Librarian, R.C.S. Eng.

Jan. 19th, 1924.

*** In THE LANCET of July 16th, 1921, we referred briefly to the pathetic story which Mr. Plarr details. —ED. L.

GLASGOW ROYAL MEDICO-CHIRURGICAL SOCIETY.—On Friday, Jan. 11th, this Society met in the Glasgow Royal Maternity and Women's Hospital, with Dr. A. Maitland Ramsay, the President, in the chair. The meeting took the form of a clinical night and the following demonstrations were given by the members of the staff of the hospital. Dr. J. Norman Cruickshank demonstrated a number of specimens illustrating the birth hæmorrhages of the infant, and explained their mode of production. He gave the results of the analysis of 400 post-mortem examinations carried out in the research department of the hospital, and showed the incidence of tentorial tears and of the various grades and types of hæmorrhage met with. The frequency of still-birth associated with each type of lesion was also pointed out. Two other series of preparations were also shown—one illustrating developmental anomalies and diseases of the new-born, and the other illustrating some of the maternal lesions in the toxæmias of pregnancy. Dr. Douglas M. Lindsay demonstrated two new obstetrical instruments—(1) a "decapitating thimble" to facilitate the operation of decapitation, and (2) a new type of obstetric forceps. Dr. S. Cameron performed Cæsarean section on a case with marked pelvic contraction. The cases shown included the following:—Dr. A. N. McLellan: A case of exophthalmic goitre complicating pregnancy. Dr. R. A. Lennie: Two cases of cardiac valvular disease associated with pregnancy. Dr. John Hewitt: Cases of albuminuria in pregnancy. Dr. James H. Martin: A series of ante-natal cases. Dr. James Hendry: Two cases of rupture of the uterus, and one case of bronchitis complicating the puerperium. Dr. Donald McIntyre: A series of post-natal cases.

Obituary.

EDWARD EMRYS-ROBERTS, M.D. LIVERP.

WE have to record with regret the death on Jan. 15th of Prof. E. Emrys-Roberts, at Penarth, at the early age of 45. Prof. Emrys-Roberts held the chair of Pathology and Bacteriology in the National School of Medicine of the University of Wales, and was pathologist to the Cardiff Royal Infirmary. Born in 1878, he was the eldest son of Mr. E. S. Roberts, of Dawlish. He began his medical studies at Liverpool, and took the degrees of M.B., B.Ch. at the old Victoria University in 1902. During his student days he served as a dresser with the Welsh Hospital attached to the Field Force in the South African War, and obtained the medal with three clasps. On his return he worked as a research scholar for three years on gynæcological pathology in the University of Liverpool, and graduated M.B., B.Ch. Liverp. in 1904 and M.D. in 1908. After acting as sub-curator of the pathological museum in Liverpool, he was appointed demonstrator of pathology in the University of Bristol and pathologist to the Bristol General Hospital. He proceeded in 1910 from Bristol to Cardiff, on his election to the professorial post which he held till his death. During the war he served with the First Army from 1915–18 in command of the Welsh Mobile Pathological Laboratory in France.

An article dealing with status lymphaticus by Prof. Emrys-Roberts appeared in the *Journal of Pathology and Bacteriology* in 1914, and he was secretary of the committee of the Medical Research Council appointed to investigate this condition. He also wrote in 1920 in the *Journal of the Royal Army Medical Corps* on the use of horse serum by inoculation in the treatment of sepsis; and was recently interested in the study of anthracosis. He was responsible for organising at the Cardiff Royal Infirmary a department of pathology in preparation for the completion of the School of Medicine, a development which he anxiously looked forward to and just lived long enough to see accomplished; in him the young school has lost a keen supporter and an indefatigable teacher. The Cardiff Medical Society owed him much; he was its senior secretary and enthusiastic in his work for it. Apart from his professional researches, his chief interests lay in ethnology and archæology. He was local correspondent of the Ancient Monuments Board for Wales, and local secretary of the Cambrian Archæological Association.

Prof. Emrys-Roberts, on account of a dysenteric condition contracted while abroad, had for some time been in imperfect health; and last autumn he himself was the first to diagnose that he had developed a serious condition which was only confirmed, but could not be alleviated, by operative procedure. He leaves a widow and six children.

ARTHUR CHARLES ROPER, F.R.C.S. EDIN.

BY the death of Mr. A. C. Roper, consulting surgeon to the West of England Eye Infirmary, on Jan. 11th, in his sixty-sixth year, the medical profession has sustained a great loss. His keen many-sided interests, his fine public and professional work, his sound judgment, his tact and kindness of heart, had made him many friends and earned him a high place in public esteem. He was a son of Mr. Charles Harriot Roper, who was for a long period a leading Exeter surgeon. Arthur Charles Roper received his early education at the Old Mount Radford School, of which his grandfather was joint principal, and began his medical career at St. Bartholomew's Hospital, London, where he obtained the M.R.C.S. in 1880. The following year he took the degrees of L.R.C.P. Edin. and L.M., and returned to Exeter to take over the practice of his father, who died in the spring of 1881. Shortly afterwards Mr. Roper was elected a member of the staff of the West of England Eye Infirmary, and his long connexion with that institution—since 1881—is associated with his position as one of the leading ophthalmic surgeons of the West of England. He was a member of the Oxford Ophthalmological Congress, and president, in 1923, of the South-West of England Ophthalmological Society. But he was also deeply interested in general surgery, and had a wide consulting practice. In the British Medical Association he played an active part, and was president of the South-Western Branch. He always took the greatest interest in the Royal Devon and Exeter Hospital, to which he had been surgeon since 1896, and consulting surgeon since 1921, and he was at one time surgeon to the Exeter Lying-in Charity. He was oculist and consulting surgeon to the Cottage Hospitals of Exmouth and Sidmouth, ophthalmic surgeon to the West of England Blind Institute, consulting surgeon to the Western Counties Institution at Starcross, and also to the Exeter Dispensary. In 1922 he gave up private practice, but continued his work as consultant oculist and surgeon. Mr. Roper, among his medical writings, contributed several articles to THE LANCET. A paper on the Enucleation of the Eyeball with Intra-orbital Injection of Cocaine appeared in our columns in 1888, and in 1922 he published the result of 489 cases of cataract extraction (THE LANCET, 1922, i., 625; and 1907, ii., 1679).

As Mayor of Exeter (1920 to 1921) he took a leading part in organising an appeal to the citizens on behalf of their hospital, and was largely instrumental in securing for the institution a sum of nearly £6500. In recognition of this service one of the wards of the new children's bungalow was named after him "The Arthur Roper Ward." In 1919 he received from the King of the Belgians the Médaille du Roi Albert for his work in aiding generally and acting as honorary oculist for the Belgian refugees in Devon and Cornwall.

In the musical world he was equally public-spirited, and his fine baritone voice was welcomed at many a concert. He was for about 45 years a member of the cathedral voluntary choir, and he had long been joint secretary of the Western Counties Medical Association. Enthusiastic in all he took up, he was a well-known croquet player and an ardent golfer. He was also an excellent actor, and took a prominent part in the formation of the Exeter Dramatic Society.

Mr. Roper is survived by a widow, two sons, and two daughters. One son was killed in the war, having won the M.C. Another son, Dr. F. A. Roper, is now physician to the Royal Devon and Exeter Hospital.

SIR ARCHIBALD DOUGLAS REID, K.B.E., C.M.G., M.R.C.S. ENG.

Sir Archibald Reid, superintendent of the X ray department of St. Thomas's Hospital, died on Jan. 15th at Chur, Switzerland, in his fifty-third year. He was the only remaining son of Dr. Douglas A. Reid, late of Tenby, and was born in 1871. He received his medical education at King's College Hospital, and qualified as M.R.C.S., L.R.C.P. in 1901. From the beginning of his career he specialised in X ray work and in 1920 took the diploma of medical radiology and electrology at Cambridge. He contributed much to the study of his particular branch of medicine, and during the war from 1915 to 1919 rendered valuable service as President of the War Office X Ray Committee. In 1917 he was created C.M.G., and in 1919 he received the further honour of K.B.E. As a consulting radiologist he held appointments in many hospitals, among them the Queen Alexandra Military Hospital at Millbank and the Royal National Hospital for Consumption at Ventnor, and was radiographer to the Evelina and Paddington Green Hospitals for Children, and to the Royal Westminster Ophthalmic Hospital. In King's College Hospital he was medical officer in charge of the X ray department. In 1911–12 he was President of the Electro-Therapeutic Section of the Royal Society of Medicine, and in 1920–21

esident of Society of Radiologists. At the Seventnth International Congress of Medicine he held the st of joint secretary, and he was an hon. member the American Roentgen Ray Society. At the time his death he was charged with the radiological amination of the mummy of Tut-Ankh-Amen, cooperation with Dr. D. E. Derry, as we announced ently in our columns.

Sir Archibald Reid's scientific publications included icles in several standard text-books on "X Ray agnosis of Calculi," "Skiagraphy in Urinary rgery," and "The Treatment of Rodent Ulcer." s opening paper at the Bilingual Congress of Radioy and Physiotherapy on "The Abnormal Stomach" peared in the *Archives of Radiology and Electrology* 1922. He was editor of "Localisation and Extracn of Projectiles" (Ledoux-Lebard and Ombredanne). In personal tribute to his memory, a friend and league, S. M., sends us the following appreciation his character and work: "That Archibald Reid ould be struck down is difficult to realise, although se of us who knew him well have been conscious a long time that all was not well with him. Full of rgy, almost boy-like in his enthusiasms—a new ce of apparatus would send him off into great ilation—he was a man of wonderful personality. om the most absolute fooling he would turn at once matters of grave moment. He was a born ganiser, and his work in connexion with the new stitute of Radiology—alas! he has not lived to see it great meeting ground for all matters and persons sociated with the science he loved so well—was gantic. He was very fond of telephoning in the late ening, and conversations became so lengthy as to come a standing joke. One evening I went to his use and found him lying full length on an easy an with the telephone comfortably at his elbow. do not think Reid had an enemy. Many people til they knew him well were inclined to resent his idency to sharpen his wits on them, but there was t an ounce of malice in it. His place will not idily be filled, and we all feel the poorer for his loss"

IOMAS WILLIAM THURSFIELD, M.D. ABERD., F.R.C.P. LOND.

Dr. T. W. Thursfield, of Leamington, who died Jan. 14th, had reached his eighty-fifth year, and ough for some years retired from the active practice his profession, had retained in full degree unimired his mental and intellectual faculties. He was e son of a medical family, members of which have actised in the Valley of the Severn, in Worcesterire, and in Warwickshire for more than a century. s father, a doctor in practice at Kidderminster, ed when his son was just over 16. Thomas Thursld went to the University of Aberdeen, and passed e examinations for a medical degree some weeks fore his twenty-first birthday. After graduation studied his profession in London and in Paris, d acted as assistant in several practices, until he ok charge of a private patient whom he accomnied on a voyage to Australia. There his patient ed, and after some time spent in New South Wales returned to this country, and in 1866 settled in actice in Leamington. Then after some years of neral practice he passed the examination for the R.C.P. Lond., and entered upon a consulting actice, which in his best days included the neighurhood and the whole of South Warwickshire. became a Fellow of the College in 1890. In 1882 was elected to the staff of the Warneford Hospital Leamington, and after serving for many years ired from the active staff in 1911, and became nsulting physician. In the following years he voted himself to the interests of the institution, to ich he was so sincerely attached, serving on the mmittees of the governing body. In his prossional life he held many other appointments in amington and the neighbourhood.

His activities were, however, not limited to his ofessional work. He was always a strong politician, and took a keen interest in municipal affairs. In politics a Liberal, he became a Liberal Unionist, and remained Unionist, but with decided Liberal, even Radical, tendencies. In municipal business he served many years as town councillor, alderman, and in 1894–1897 as mayor of the borough. He was also a borough and a county magistrate. Perhaps his keenest interest, next to that of the hospital, was in the free library, to which he gave willing service nearly the whole of his life in Leamington.

He had outlived the greater part of his own generation both in and outside the profession, and the loss of his wife, to whom he had been happily married for more than 50 years, left him lonely in his last years, a loneliness often relieved by the welcome visits of friends. He died in sleep after an operation which was undertaken at his urgent request with the full knowledge that his strength, undermined by recent illness, was hardly sufficient to afford expectation of recovery. He left three sons, of whom one is in the medical profession.

CHARLES KIRK CLARKE, M.D., LL.D. TORONTO.

THE death of Dr. C. K. Clarke, since 1907 professor of psychiatry in the University of Toronto, at the age of 69, will be regretted by many of his co-workers in psychiatry in this country as well as in Canada, the more so as many of them had the opportunity of meeting him in London last summer. He was born at Elora, Ontario, and educated at the Elora High School and the University of Toronto, graduating M.B. Toronto in 1878 and M.D. in 1879. Even before qualification he showed a leaning towards psychiatry, becoming clinical assistant to the Toronto Lunatic Asylum in 1874. In 1879 he was made assistant physician to this institution, and after an interval of 15 years, during which period he gained experience as assistant medical superintendent at Hamilton and Rockwood Asylums, was appointed its medical superintendent. He held this position for six years, becoming medical superintendent of the Toronto General Hospital in 1911. While at Kingston Dr. Clarke acted as professor of mental diseases in the Queen's University, which made him an honorary LL.D. He was largely responsible for the establishment in connexion with Rockwood Asylum of a convalescent and nurses' home. Dr. Clarke was appointed Dean of the Medical Faculty of the University of Toronto in 1908, and held this post for some years. His publications are numerous not only on his special subject, but also on ornithology. For a time he was associate editor of the *American Journal of Insanity*. Dr. Clarke was known to be as much interested in the subject of mental hygiene as in that of insanity, and it caused no surprise that for the fourth Maudsley lecture,[1] delivered by him on May 24th, 1923, before the Medico-Psychological Society of Great Britain and Ireland, he took as title Mental Hygiene in Canada. One of the questions on which he felt strongly was that indiscriminate immigration to the colonies had its dangers, since the host of immigrants drifting from the old world always contains an undue proportion of defectives and mentally diseased persons. The training of psychiatrists was another subject which Dr. Clarke made specially his own. In Toronto there has been developed under his direction an optional course in psychology and psychiatry covering five years—the word "optional" signifying that less than half the candidates who apply to take this course are selected to enjoy its privileges. His desire adequately to educate the expert psychiatrist was associated with a strong impulse to promote the education of the public to demand such expert knowledge, and this work is being undertaken by the Canadian National Committee for Mental Hygiene over which Dr. Clarke presided. The loss sustained in his death is indeed severe, but it is certain that since the foundations of his work were well laid they will form the

[1] THE LANCET, 1923, i., 1123 and 1139.

basis of a widespread advance in efforts to eliminate mental disease from the community in the old and the new worlds.

JAMES TURTON, F.R.C.S. ENG.

Dr. Turton, who died on Jan. 11th at the age of 68, had been for many years a leading medical man in Brighton. He studied medicine with distinction at Charing Cross Hospital, qualifying L.S.A. in 1879 and became M.R.C.S.Eng. in the following year. Later he was elected a Fellow of the College. Dr. Turton went to Brighton in the early 'seventies as an apothecary to the late Dr. Richard Rugg, whose daughter he married. In 1886 he became identified with the Volunteer movement at Brighton. From acting surgeon he rose to the rank of surgeon-major, and retired in 1912 with the honorary rank of Colonel and the Volunteer decoration. He also served in the Army Medical Reserve, which he joined in May, 1888, holding the rank of surgeon-captain. In 1894 he raised the Sussex and Kent Volunteer Infantry Brigade Bearer Company, which was the first bearer company raised in the Volunteer Force, and he commanded that company until 1904, when he became Brigade Surgeon-Lieut.-Colonel of the Sussex and Kent Volunteer Infantry Brigade. At the outbreak of the Boer War his duties included the examination of the Sussex Militia; also the men who volunteered their services; and during the late war he was medical officer at the Royal Pavilion, Brighton, when that historic building was taken over as the Indian Hospital.

Dr. Turton took a keen interest in everything appertaining to the welfare of Brighton and for a period was a member of the town council. He was in demand as a vigorous speaker, and his knowledge of men and affairs secured for him what he had long coveted, a seat on the judicial bench.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

The Labour Government.

THE Government were defeated on Monday on the Labour Party's vote of "No Confidence" by 328 votes to 256. The Right Hon. J. RAMSAY MACDONALD having accepted the King's Commission to form an Administration, the House of Commons met on Tuesday, Jan. 22nd, and adjourned until Feb. 12th.

HOUSE OF COMMONS.

WEDNESDAY, JAN. 16TH.

Unqualified Persons Practising Medicine.

Mr. SPERO asked the Minister of Health if he was aware of the fact that, owing to advertisements issued by unskilled, untrained, and unqualified people practising medicine and surgery claiming special knowledge and ability to relieve and cure such dreaded diseases as cancer, &c., many lives had been seriously endangered and in some instances lost; and whether he was prepared to take immediate steps to prohibit them from advertising in any shape or form.—Sir W. JOYNSON-HICKS replied: My attention has been called to a recent case, where it appears that a patient may have been misled by an advertisement, but no information is available as to the extent of the evil to which the hon. Member refers, and I doubt whether legislation to prohibit unqualified medical practice would be regarded as uncontroversial.

THURSDAY, JAN. 17TH.

Mentally Afflicted Ex-Service Men.

Mr. GRAY asked the Minister of Pensions whether he was in a position to make a statement with regard to ex-Service men occupying the status of pauper lunatics; and whether he could inform the House the additional cost that would fall upon this country if pensions were granted to them as to other ex-Service men mentally afflicted.—Major TRYON replied: All men suffering from disabilities, whether mental or not, due to or remaining worsened by service are admitted to the full benefits of the Royal Warrant. But, as I have already stated, I am not in a position to recommend that an exception should be made in favour of any particular disability which would authorise my department to accept responsibility for men suffering from a condition not connected with their war service.

Mr. LANSBURY asked the Minister of Pensions how many ex-Service men suffering from mental disability have been discharged from maintenance by his department and transferred to the care of the Poor-law or other local authorities.—Major TRYON replied: The number of men whose mental condition could not be regarded as in any way due to or worsened by service, but who had benefited by the temporary concession in their favour which came to an end some 18 months ago, is 771.

Physically and Mentally Defective Children.

Mr. ROBERT MORRISON asked the President of the Board of Education how many physically and mentally defective children were on the roll of London special schools; and whether the figures showed an increase or decrease on the preceding year.—Mr. E. WOOD replied: The number of children on the rolls of London special schools for physically and mentally defective children for the week ending Dec. 21st 1923, was 12,243, showing a decrease of 328 on the figures for the similar week in 1922.

Pollution of the River Lee.

Mr. HERBERT MORRISON asked the Minister of Health whether he was aware that the pollution of the River Lee where it passed through the Metropolitan Borough of Hackney, was still exceedingly serious; that, despite prosecutions of local authorities alleged to have let crude sewage into the river, little or no improvement was taking place; and that the legal position in regard to the separate powers of the Middlesex County Council had created confusion so far as the county of Middlesex was concerned; whether, from the point of view of public amenity, public health, and the creation of much-needed employment, he would take steps to bring urgently before the Cabinet the question of putting in hand a main drainage system as satisfactory as that existing in the County of London, and in relation to that of London, in respect of the urban districts of Edmonton, Enfield, Leyton, Walthamstow, and other districts affected.—Sir W. JOYNSON-HICKS replied: I am aware of the conditions affecting the River Lee at Hackney but steps are now being taken which should result in a marked improvement. At Enfield works are in hand for which a loan of £53,000 has been sanctioned, and the Edmonton Urban District Council also have decided to carry out improvements at a cost of approximately £90,000. The local authorities of Walthamstow and Leyton are negotiating with the London County Council with a view to the reception of their sewage into the metropolitan system.

Convalescent Centre at Barry.

Mr. BARKER asked the Minister of Pensions if it was proposed to close the Prince of Wales Convalescent Centre at Barry; and, if so, would he have the question reconsidered on the ground that the trainees would lose the advantages of technical training or be transferred to English centres remote from their homes.—Major TRYON replied: It is anticipated that the requirements for accommodation at convalescent centres for treatment and training will not justify the retention for the whole of the current year of all of the four separate centres. A decision as to the centre or centres to be closed, and the date of closing must await further detailed examination of the applications received up to the date of the closing of the waiting list on the 31st ultimo. The hon. Members may rest assured that in the event of a centre being closed, suitable provision will be made for completing the treatment-training of the men, among whom transfers from one centre to another for various reasons are already not uncommon. The number of men who received treatment and training at Barry in 1923 was 569.

Specialist Treatment for Neurasthenia.

Mr. ROBERT RICHARDSON asked the Minister of Pensions whether any order had been issued prohibiting treatment by specialists in the case of men suffering from neurasthenia and assessed at 20 per cent. or under; and, if so, did the medical advisers of the Ministry consider that treatment was unnecessary in these cases.—Major TRYON replied: The answer is in the negative. The provision of treatment is undertaken by my department in all cases of neurasthenia in which a neurological medical officer of the Ministry considers it to be necessary.

Smoke Abatement.

Sir HARRY BRITTAIN asked the Minister of Health whether in view of the acknowledged evil effect upon the health of the community and the wastage of money caused by ever recurring fogs in our great cities, he was able to state that his department was doing all possible to expedite the passage into law of the Smoke Abatement Bill.—Sir W. JOYNSON-HICKS replied: It is proposed to reintroduce the Bill to which my hon. friend refers, and I hope it may be found possible to secure its passage into law during this session.

Incapacity and Death Certificates.

Mr. NAYLOR asked the Minister of Health whether his attention had been drawn to the objections raised by the issue of the new incapacity certificates (form Med. 40*b* and form Med. 40*c*), on the reverse side of which was a form of death certificate; and, if so, whether, seeing that these certificates were handled by the patients, he would take steps to have the form of death certificate issued separately.—Mr. W. A. JENKINS asked the Minister of Health if he was aware that the new issues of insurance incapacity certificate

ms Med. 40*b* and form Med. 40*c* contain on the reverse le a form of death certificate; and, in view of the pain, xiety, and distress which might be caused to the patient d his family, would he give instructions for these objec- nable forms to be immediately withdrawn.—Sir W. YNSON-HICKS replied: The form was prepared after nsultation with representatives of approved societies and surance practitioners, but I am referring it to the approved cieties Consultative Council for further consideration.

Dr. HADEN GUEST, in the course of the discussion on the abour Vote of Censure on the Government in the debate the address, said he had in his hand a curious piece of nk paper, which was a certificate from the National Health surance Authority. On one side there was a certificate at stated to so-and-so to whom it was addressed, "I certify at I have examined you and that you are unfit for work." low that there was a certificate stating that so-and-so "in a state of convalescence." On the reverse side of the me paper there was a certificate which ran as follows: Certificate of death of insured person." He urged that is was a failure to appreciate the point of view of the fortunate patient; a failure of contact with those con- tions of narrow living and poverty which were the lot of the ople to whom these certificates were given. In this rtificate the definite suggestion was conveyed to any tient that the end of this particular period of medical eatment was the certificate of death for the insured person.

Sir W. JOYNSON-HICKS: Perhaps the hon. gentleman will low me. There were two questions addressed to me this ternoon on this subject. It appears the proposal was ade by London medical men and had the approval of the cieties. As soon as I heard of it I suspended the issue of e certificate, and I have referred the matter to the nsultative Council of these societies.

Dr. GUEST said he was very glad to hear that this extremely fortunate document had been recalled.

FRIDAY, JAN. 18TH.

Calf-lymph.

Mr. ROBERT YOUNG asked the Minister of Health whether was aware that it had been stated that private medical actitioners experienced difficulty in obtaining supplies of ycerinated calf-lymph of the same guaranteed purity as at supplied to public vaccinators by the Ministry of Health; d whether, seeing that many persons preferred to be ccinated by their own medical advisers, he would take eps to secure the necessary powers to ensure that supplies such lymph would be procurable at a reasonable charge private medical practitioners.—Sir W. JOYNSON-HICKS plied: As regards the first part of the question, I am lvised that there is no difficulty in obtaining from reputable ms supplies of glycerinated calf-lymph of reliable quality. he action suggested in the second part of the question ould involve a large and costly extension of the present overnment supply, for which, as at present advised, I see need.

Unfit Houses.

Mr. VIANT asked the Minister of Health if he would troduce legislation amending the Public Health Act, 1875, ction 91, by extending the definition of nuisances to include mmon defects, as per the manual of the Ministry on unfit uses and unhealthy areas, volume 1, page 2 (general pairs), thus enabling local authorities to deal with property which grates, stoves, windows, window-frames, doors, walls, d ceilings were defective.—Sir W. JOYNSON-HICKS replied: he Local Authority had power under Section 28 of the ousing, Town Planning, &c., Act, 1919, as amended by ction 10 of the Housing, &c., Act., 1923, to deal with orking-class houses which were not in all respects reasonably for human habitation, and those powers should ordinarily sufficient.

Deaths from Small-pox.

Sir W. JOYNSON-HICKS informed Mr. LEACH that six eaths from small-pox were registered during the year 923, the outbreak being fortunately of a mild character. s regarded chicken-pox, figures are at present only available r the first three-quarters of the year; the number of eaths during that period was 41. During the first 11 onths of the year, eight deaths were attributed to vaccina- on, while five deaths attributed to other causes were nsidered to be associated with vaccination. The figures r December were not yet available.

Forms Med. 40b and 40c.

Mr. ALFRED T. DAVIES asked the Minister of Health hether his attention had been directed to the new issue f insurance incapacity certificates, forms Med. 40b and fed. 40c, on the reverse side of which is a death certificate; nd whether, in view of the general opinion of medical men nd the distinctly indelicate nature of the inclusion of such eath certificate, any action was to be taken.—Sir W. OYNSON-HICKS replied: I am arranging for the issue of ew certificates at an early date.

Somerset Small-pox Hospital.

Mr. FREDERICK GOULD asked the Minister of Health whether, in view of the fact that the Somerset County Council proposed to erect a small-pox hospital in a purely milk-producing parish where there was no public supply of water and no system of public sewerage, and having regard to the highly infectious nature of this disease and the strong opposition of the parishioners, he would refuse his consent to its erection.—Sir W. JOYNSON-HICKS replied: A public inquiry was held in November last by one of the medical officers of my department into the proposal of the Somerset County Council to appropriate certain land for the erection of a small-pox hospital, and after considering his report I sanctioned the appropriation of the land for this purpose. No further consent on my part will be required unless the county council apply for sanction to a loan to defray the cost of providing the hospital.

Disease Aggravated by War Service.

Mr. CLUSE asked the Minister of Pensions if he would state the number of men who during the past three years have had their diagnosis changed from attributed to service to aggravated by service; and how many of these had subsequently lost their pensions because the aggravation had passed away.—Major TRYON replied: During the past three years in the case of less than 2 per cent. of the men in receipt of pension, or about 18,000 men, has a disability been found on medical grounds to have been aggravated or worsened by service, instead of attributable to it. In 3500 cases, on the other hand, the diagnosis has been changed from aggravated to attributable. The records of the Ministry do not enable the last part of the question to be answered.

Amputation of Both Legs.

Major TRYON informed Mr. ROBERT MORRISON that men who had had both legs amputated at or above the middle of the thigh were entitled to the maximum constant attend- ance allowance of 20*s.* a week.

Small-pox or Chicken-pox?

Mr. BROAD asked the Minister of Health whether, in view of the fact that the disease notified as small-pox during 1923 was so mild as to be less fatal than chicken-pox, he was assured that it really was small-pox.—Sir W. JOYNSON-HICKS replied in the affirmative.

Fee to Midwives.

Capt. W. BENN asked the Minister of Health what security was provided for the payment to midwives of their fee out of maternity benefit drawn by insured persons under the Health Insurance Act.—Sir W. JOYNSON-HICKS replied: Beyond providing that the maternity benefit shall in every case belong to the mother, the Act does not specify any particular manner in which the money must be expended, and consequently there is no special provision with regard to the payment of a midwife's fee. The midwife has, however, the advantage of knowing that the woman will receive a fairly substantial sum by way of maternity benefit, and that she would, therefore, ordinarily be in a position to pay a reasonable fee in respect of the attendance she receives.

Medical News.

UNIVERSITY OF LONDON: FACULTY OF MEDICINE.—A course of four lectures on Cancer will be given in the Governors' Hall at St. Thomas's Hospital, S.E., by Dr. J. A. Murray, on Feb. 21st and 28th, and March 6th and 13th, at 5 P.M. The Provisional Syllabus is as follows: Lect. I.—Malignant new growths (carcinoma, sarcoma, endothelioma) of man and animals; separation from infective granulomata from benign tumours; microscopic anatomy of fully developed tumours; mode of spread and dissemination; unicentric and multicentric origin; multiple primary growths; frequency; age incidence; international statistics; increase of cancer; organ incidence; occupational cancer. Lect. II.—Experimental study of causation; virus sarcomata of fowls; spiroptera carcinoma; cysticercus sarcoma, X ray sarcoma, tar carcinoma, and sarcoma; relation to age incidence; chronic irritation; duration and intensity of stimulus; predisposition. Lect. III.—Regeneration, wound-healing and repair; irritative hypertrophy; equivocal microscopic appearances resembling new growths in early stages of development; stimulus to growth by injury; initiation of repair, activator substances; presence in rapidly growing tumours; acceleration of carcinogenesis by injury; resistance to a second production of primary cancer. Lect. IV.—Evidence of a cellular change in the malignant transformation; behaviour as new individual of primary growth; evidence from transplantation experiments; permanence of parenchyma characters; immunity to

transplanted growths: spontaneous cure; study of tumour metabolism; respiration, carbohydrate metabolism, protein metabolism, specific dietary deficiencies; rôle of diet in causation and treatment. At the first lecture the chair will be taken by Sir George Makins. The lectures, which will be illustrated by lantern slides, are addressed to advanced students of the University and to others interested in the subject. Admission is free without ticket.

University College.—A course of seven free public lectures on the Current Work of the Biometric and Eugenics Laboratories will be held on Wednesdays, at 6 P.M., from Feb. 13th to March 26th inclusive. On Feb. 13th Prof. Karl Pearson, F.R.S., will lecture on the Contributions of Sir Francis Galton to Photography: on the 20th Dr. M. Greenwood will discuss the Biometric Study of Cancer. Miss Ethel M. Elderton will speak on Inheritance in Finger-prints and the Possibility of their Use in Cases of disputed Paternity on the 27th, and Dr. Julia Bell on Colour Vision and Colour Blindness from the Historical Aspect on March 5th. Mr. Egon S. Pearson will discuss Birth Intervals as a Factor in the Size of the Family on the 12th, and Dr. Percy Stocks the Influence of Social Status and Physical Development on the Characters of the Blood on the 19th, while on the 26th Prof. Pearson will give the concluding lecture on the Contributions of Sir Francis Galton to Psychology. The lectures will be delivered in the theatre of the Biometric and Eugenics Laboratory at University College, Gower-street, London, W.C.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—A special course of clinical lecture-demonstrations, including the use of the ophthalmoscope, will be given at the Central London Ophthalmic Hospital, Judd-street, from Jan. 28th to Feb. 22nd. Also a short course in dermatology, consisting of clinical demonstrations each afternoon, will take place at the Hospital for Diseases of the Skin, Blackfriars, from Jan. 28th to Feb. 10th, and special clinical lectures on the more important diseases of tropical countries will be given on Tuesdays and Thursdays at the London School of Tropical Medicine, Endsleigh-gardens, from Feb. 5th to Feb. 29th. The syllabus of the two weeks' special intensive course at the North-East London Post-Graduate College, Prince of Wales's General Hospital, Tottenham, is now available and can be obtained from the Secretary to the Fellowship of Medicine or from the Dean of the College. It includes demonstrations of clinical methods and cases and work in the general and special departments of the hospitals, and, in addition, a lecture each afternoon at 4.30 P.M. to which members of the North-East London Post-Graduate College and of the Fellowship of Medicine are invited. For those desiring to follow a course of study in the diseases of children, a special combined course has been arranged for the whole of February by the four following institutions—viz., Paddington Green Children's Hospital, Royal Waterloo Hospital for Children and Women, Victoria Hospital for Children, and the "Children's Clinic" at the Western General Dispensary. The programme consists of lectures and clinical demonstrations on medical and surgical diseases of children, including all the special departments and clinical laboratory demonstrations. Copies of the syllabus of any of the above courses with full particulars regarding fees, &c., can be obtained from the Secretary to the Fellowship of Medicine, at 1, Wimpole-street, London, W. 1.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.—A dinner will be held in the Hall of the College, 9, Queen-street, Edinburgh, on Feb. 15th, at 7.15 for 7.30 P.M.

ROYAL SANITARY INSTITUTE.—A reception will be held at this institute, 90, Buckingham Palace-road, London, S.W., on Feb. 5th, at 5 P.M., to meet medical officers visiting this country, under the auspices of the Health Organisation of the League of Nations, to study public health administration.

EUGENICS EDUCATION SOCIETY.—A lecture on Eugenics in the United States will be delivered by Dr. Harry H. Laughlin, Director of the Carnegie Institute of Washington Eugenics Record Office, at the rooms of the Royal Society, Burlington House, Piccadilly, London, W., on Jan. 29th, at 8.30 P.M., Prof. E. W. MacBride, F.R.S., presiding. All interested in the subject are invited to attend.

SMALL-POX IN ENGLAND AND WALES.—The number of notifications of small-pox received by sanitary authorities in England and Wales during the week ended Jan. 12th was 80, distributed as follows: Derbyshire 40 (Bolsover 1, Chesterfield 11, Heanor 3, Ripley 1, Swadlincote 7, Blackwell R.D. 14, Hartshorn-and-Seals R.D. 1, Shardlow R.D. 2); Gloucestershire 17 (Gloucester 1, East Dean R.D. 16); Northumberland 1 (Ashington); Notts 19 (Hucknall 5, Kirkby-in-Ashfield 12, Basford R.D. 2); Yorks, West Riding 3 (Adwick-le-Street).

THE University of Edinburgh is to receive the sum of £48,000 as residue of the estate of the late Mr. Thomas McKie, advocate, Edinburgh, who died in 1909. Part of the bequest is to be devoted to scientific medical and surgical research.

BATH CLINICAL SOCIETY.—A meeting of this Society was held at the Royal United Hospital on Jan. 4th, Dr. W. P. Kennedy, the President, being in the chair. Dr. R. G. Gordon exhibited a case of subacromial bursitis, showing the typical signs described by Buckley; also a case of Charcot's knee-joint in a case of tabes with marked abnormal mobility. Mr. W. G. Mumford showed (1) a case of multiple staphylococcal osteomyelitis; (2) a case of swelling in both breasts due to rapidly growing carcinoma; and (3) a specimen of a pregnant uterus removed for a cervical fibroid. Dr. V. Coates showed a case which had been operated on four years previously when an inoperable cancer of the stomach was diagnosed. The history of miscarriages suggested that this was really a case of gastric syphilis. Dr. F. G. Thomson showed a case of aortic disease with fibrillation.

SOFIE A. NORDHOFF-JUNG CANCER RESEARCH PRIZE.—In the early part of last year (see THE LANCET, 1923, i., 481) we recorded the gift by Dr. Nordhoff-Jung, of Washington, Columbia, U.S.A., of an annual prize of $500, designed to encourage researches into the ætiology, prevention, and treatment of cancer. The Commission on the award was to consist of Profs. Borst, Doederlein, v. Romberg, and Sauerbruch, all of the University of Munich, and the prize was to be awarded for the first time at the end of 1923 in recognition of the most conspicuous work in the world literature bearing on cancer research, done at a time antecedent to the allotment of the award. The first recipient of the honour is Prof. Johannes Fibiger, professor of pathological anatomy at the University of Copenhagen. Prof. Fibiger has demonstrated, following repeated experimentation, that parasites play an important rôle in the formation of certain types of tumours in the proventriculi of rats. In the citation of the committee it is pointed out that it was Fibiger who first met with success in artificially inducing malignant tumours through external irritations, and he has thus thrown wide new avenues to future findings. Though the earlier results of Fibiger's work date back a number of years, he unremittingly laboured towards an interpretation of the significance of parasitic irritants in malignant tumour formation, likewise of mechanical and chemical irritants. Fibiger and his associates have contributed generously to the literature of cancer production through the feeding to rats of oats and the application of tar to their tissues.

THE LATE DR. O. M. DE JONG.—Dr. Oscar de Jong, whose death is reported from Liverpool, had only just been appointed medical superintendent of the new Seamen's Dispensary in Liverpool, which is intended to provide the facilities of an up-to-date "Lock Department," along with advice and out-patient treatment for seamen suffering from ailments of all kinds. Dr. de Jong qualified M.B., Ch.B. Manch. in 1914, taking his D.P.H. Manch. in 1915. At the time of his death he was but 31 years of age, but gave promise of a distinguished career in dermatology. At one time assistant M.O.H. for Liverpool and Salford and clinical assistant in the skin department of the Royal Infirmary, he was also medical officer in charge of the venereal diseases clinic at the Royal Southern Hospital.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear it if reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, Jan. 28th.

ODONTOLOGY: at 8 P.M.

Casual Communication:

Mr. P. S. Campkin: A Lens Permeable by Ultra-Violet Ray—Used by Patient.

Paper:

Sir Frank Colyer: A Note on Caries of the Teeth of Old-World Monkeys (with lantern demonstration illustrating Irregularities of the Teeth of Old-World Monkeys).

Thursday, Jan. 31st.

BALNEOLOGY AND CLIMATOLOGY: at 5.30 P.M.

Papers:

Dr. W. J. Smith Jerome: On the Physiological Action of the Dry Inhalation of Sodium Chloride; an Italian Method of Treatment.

Dr. A. G. S. Mahomed: On Sea-water Injections.
Members of the Section will dine together at the Welbeck Hotel, Welbeck-street, at 7.30 P.M. Those desiring to be present are requested to inform Dr. C. F. Sonntag, 80a, Belsize Park-gardens, N.W. 3, not later than by the last post on Jan. 30th.

ROLOGY: at 8.30 P.M.
Clinical-pathological Evening:
Specimens: The following will be shown by:—
Mr. W. McAdam Eccles: Perirenal Tumour.
Sir John Thomson-Walker: Cyst of the Prostate.
Mr. S. G. MacDonald: Gall-stones removed from the Urinary Bladder.
Mr. A. Clifford Morson: Enormous Vesical Calculus.
Mr. W. Girling Ball: Retroperitoneal Tumour.
N.B.—Will those intending to take part please let Mr. Girling Ball know the type of case or specimen desired to be shown; also if a microscope is required.

Friday, Feb. 1st.

LARYNGOLOGY: at 5 P.M. (Cases at 4 P.M.)
Cases and Specimens:
Cases and specimens will be shown by Mr. Souttar, Mr. Peters, Mr. A. J. Wright, Mr. C. F. Beevor, Sir James Dundas-Grant, Dr. Jobson, Mr. Kelson, Sir StClair Thomson, and others.

ANÆSTHETICS: at 8.30 P.M.
Paper:
Dr. W. Howard Jones: The Use of Chloroform and the Mis-use of Ether.

Saturday, Feb. 2nd.

OTOLOGY: at 10 A.M. (Cases at 9.15 A.M.)
Paper:
Sir William Milligan: The Surgical Treatment of Suppurative and Certain Non-suppurative Affections of the Labyrinth (illustrated with lantern slides).
Cases:
Sir James Dundas-Grant: Two Cases of Radical Mastoid Operation treated Without Plastic.
Dr. T. B. Jobson: Case of Cerebral Abscess.
Other cases will be shown.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.
WEDNESDAY, Jan. 30th.—4 P.M., Sir H. Gauvain: Heliotherapy and Open-air Treatment.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W. 1.
MONDAY, Jan. 28th.—8.30 P.M., (1) Dr. G. Arbour Stephens: A Short Historical Note on Transfusion of Blood and Injection of Medicated Liquors as carried out in 1650–1700. (2) Dr. John Poynton, Mr. Twistington Higgins, and Dr. J. M. Erydone: A Paper on the Present Position of the Treatment of Pyloric Stenosis in Infancy.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.
MONDAY, Jan. 28th to FRIDAY, Feb. 1st.—CENTRAL LONDON OPHTHALMIC HOSPITAL. Clinical Lecture Demonstrations every afternoon. Mon. 2 P.M., Mr. Oliver; Tues., 2.30 P.M., Mr. Gibb; Wed., 2.30 P.M., Mr. Levy; Thurs., 2.30 P.M., Mr. Cunningham; Fri., 4.30 P.M., Mr. Williamson-Noble.—THE HOSPITAL FOR DISEASES OF THE SKIN, Blackfriars. Clinical Instruction in the Out-patient Department every afternoon from 2.30 P.M. Tues. 5.30 P.M., Venereal Clinic. Wed., 4 P.M., Special Demonstration of Selected Cases.—WEST-END HOSPITAL FOR NERVOUS DISEASES, at 73, Welbeck-street, W. Mon., 2 P.M., Dr. Hildred Carlill: Hysteria and Other Common Neuroses. Tues., 5 P.M., Dr. Ridley Prentice: Paraplegia. Wed., 5 P.M., Mr. Lindsay Rea: Ocular Manifestations of Nervous Disease. Fri., 1.30 P.M., Sir James Dundas-Grant: Deafness in Nervous Disease.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn-fields, W.C.
MONDAY, Jan. 28th.—5 P.M., Prof. F. Cook: Observations on the "Toxæmias" of Pregnancy.
WEDNESDAY.—5 P.M., Prof. A. Fleming: Employment of Antiseptics in Treatment of Local and General Infections.
FRIDAY, Feb. 1st.—5 P.M., Prof. G. Jefferson: Injuries of the Cervical Spine.

UNIVERSITY COLLEGE, Gower-street, W.C.
FRIDAY, Feb. 1st.—5 P.M., Prof. J. Robertson: The Influence of Improved Town Planning and Housing in Public Health. (Second of three lectures.)

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.
TUESDAY, Jan. 29th.—5 P.M., Dr. Graham Little: Epithelioma.
THURSDAY.—5 P.M., Dr. H. MacCormac: Ringworm.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.
THURSDAY, Jan. 31st.—4 P.M., Mr. Tyrrell Gray: Abdominal Pain.

QUEEN CHARLOTTE'S LYING-IN HOSPITAL, Marylebone-road, N.W.
THURSDAY, Jan. 31st.—5 P.M., Mr. Bourne: Puerperal Insanity.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.
MONDAY, Jan. 28th.—10 A.M., Surgical Registrar: Surgical Pathology. 2 P.M., Mr. Simmonds: Surgical Out-patients. 2 P.M., Mr. Bishop Harman: Eye Dept.
TUESDAY.—10.30 A.M., Medical Registrar: Medical Wards. 12 noon, Dr. Burrell: Chest Cases. 2 P.M., Mr. Sinclair: Surgical Out-patients.
WEDNESDAY.—10 A.M., Dr. Saunders: Medical Diseases of Children. 12.15 P.M., Dr. Burnford: Medical Pathology. 3 P.M., Dr. Pernet: Skin Dept.
THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Dept. 12 noon, Mr. Simmonds: Demonstration of Fractures. 2 P.M., Dr. Scott Pinchin: Medical Out-patients.
FRIDAY, Feb. 1st.—12 noon, Mr. Endean: Venereal Diseases. 2 P.M., Dr. Burrell: Medical Out-patients. 2 P.M., Mr. Banks-Davis: Throat, Nose, and Ear Dept.
SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.
Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

CANCER HOSPITAL, Kensington, S.W.
WEDNESDAY, Jan. 30th.—4.30 P.M., Dr. A. Leitch: The Irritation Theory of Cancer.

LONDON SCHOOL OF MEDICINE FOR WOMEN, Hunter-street, W.C.
TUESDAY, Jan. 29th (and two following days).—5.30 P.M., Dr. Gibbon Fitzgibbon, Master of the Rotunda: The Treatment of Contracted Pelvis.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES. (At 3.30 P.M.)
MONDAY, Jan. 28th.—(At the Children's Hospital.) Dr. Armstrong: Clinical Demonstration.
TUESDAY.—(At the Southern Hospital.) Mr. Armour: Certain Diseases and Deformities of the Foot.
WEDNESDAY.—(At the Northern Hospital.) Mr. Monsarrat: Surgical Treatment of Thyroid Disease.
FRIDAY, Feb. 1st.—(At the Royal Infirmary.) Dr. J. Owen: Demonstration of Children showing Conduct Change and other Sequelæ of Encephalitis.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE LECTURES.
TUESDAY, Jan. 29th.—4.15 P.M., Mr. A. H. Burgess: Some Questions in Connexion with Prostatectomy.

SALFORD ROYAL HOSPITAL LECTURES.
THURSDAY, Jan. 31st.—4.30 P.M., Dr. C. C. Heywood: Acute Rheumatism and Rheumatic Fever.

ST. MARY'S HOSPITALS, MANCHESTER, POST-GRADUATE LECTURE. (At Whitworth-street West Branch.)
FRIDAY, Feb. 1st.—4.30 P.M., Dr. F. H. Lacey: Visit to Obstetric Wards.

UNIVERSITY OF SHEFFIELD POST-GRADUATE LECTURES.
TUESDAY, Jan. 29th.—(At the Royal Infirmary.) Mr. Pooley: Differential Diagnosis of Common Eye Conditions.
FRIDAY, Feb. 1st.—(At the Royal Hospital.) Mr. F. Wilson: Surgery of Infantile Paralysis.

MANCHESTER BABIES' HOSPITAL POST-GRADUATE LECTURES.
FRIDAY, Feb. 1st.—8 P.M., Dr. Hector C. Cameron: The Special Character of Disease in Infants.

Appointments.

ACLAND, T. D., M.D. Lond., F.R.C.P. Lond., M.R.C.S., has been appointed Honorary Consulting Physician to the Ministry of Pensions.
LAPPER, C., L.R.C.P. & S. I., Poor-law Medical Officer for Loughborough.
WHARTON, J., M.D. Camb., Hon. Ophthalmic Surgeon to the Manchester Royal Infirmary.

Vacancies.

For further information refer to the advertisement columns.

Bedford County Hospital.—Asst. H.S. £130.
Birkenhead and Wirral Childrens Hospital, Woodchurch-road.—H.S. £100.
Bolingbroke Hospital, Wandsworth Common, S.W.—H.S. £120.
Bournemouth, Holiday Home for Tuberculous Ex-Service Men.—Res. Med. Supt. £500.
Bradford City Municipal General Hospital, St. Luke's.—H.P.'s and H.S.'s. Each £200.
Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Registrar. 50 guineas.
City of London Hospital for Diseases of the Heart, Victoria Park, E.—Radiologist.
Discovery Expedition.—S. £600.
Dundee Royal Infirmary.—Hon. Asst. P. for Diseases of Skin.
Eday Parish, Orkney.—M.O. £340.
Elizabeth Garrett Anderson Hospital, Euston-road.—Asst. Clin. Pathologist. £100.
Exeter, Royal Devon and Exeter Hospital.—Sen. H.S. £250.

Gloucester, Gloucestershire Royal Infirmary and Eye Institution.—Sen. H.S. £175.
Hospital for Sick Children, Great Ormond-street, W.C.—Cas. O. Also Asst. Pathologist. Each £400.
Hull Royal Infirmary.—Sen. H.S. £200.
Lancashire County Mental Hospital, Winwick, Warrington.—A.M.O. £432.
Leeds Maternity Hospital.—Univ. Tutor in Obstetrics, &c. £300.
London Lock Hospitals, 283, Harrow-road, W., and 91, Dean-street, W.—Hon. Ophth. S.
London (Royal Free Hospital) School of Medicine for Women.—First Asst. in Obstet. and Gynæcol. Unit. £700.
Manchester Hospital for Consumption, &c.—Res. M.O. £300.
Middlesex Hospital, W.—Res. M.O.
North Marylebone School of Mothercraft, Maternity Clinic.—M.O. £1 11*s.* 6*d.* per session.
Nottingham General Hospital.—H.P. £200.
Plymouth, Devon and Cornwall Sanatorium for Consumptives, Didworthy, South Brent.—Res. Med. Supt. £550.
Queen Mary's Hospital for the East End, Stratford, E.—Hon. Asst. P.
Royal Earlswood Institution, Redhill, Surrey.—Jun. Asst. M.O. £250.
South London Hospital for Women, South Side, Clapham Common, S.W.—Asst. S.
Stockport Infirmary.—Physio-therapeutist.
Weir Hospital, Grove-road, Balham, S.W.—Asst. Res. M.O. £100.
West London Hospital, Hammersmith-road, W.—Hon. Med. Reg., Hon. Surg. Reg., and Hon. Obstet. Reg.
Westminster Hospital, Broad Sanctuary, S.W.—Asst. S.
West Riding Asylum, Wakefield.—Jun. Asst. M.O. £400.
Winsley Sanatorium, near Bath.—Sen. Res. M.O.
Wolverhampton and Staffordshire Hospital.—H.S. £150.
York City Mental Hospital, Fulford, York.—Locum Tenens. 7 guineas weekly.

The Chief Inspector of Factories, Home Office, London, S.W., announces the following vacant appointments: Nant-garedig, Carmarthen; Forres, Moray; Pershore, Worcester; Greenlaw, Berwick.

The Secretary of State for the Home Department gives notice of a vacancy under the Workmen's Compensation Act for the district of the Wrexham County Court. Applications should reach the Private Secretary, Home Office, London, not later than Feb. 9th.

Births, Marriages, and Deaths.

BIRTHS.

HARDY.—On Jan. 13th, at Beaufort-road, Edgbaston, the wife of Dr. T. L. Hardy, of a son.
WARD.—On Jan. 15th, the wife of Gordon Ward, M.D., Sevenoaks, of a daughter.

MARRIAGES.

WILSON—AYRTON.—On Jan. 12th, at Chester, Graham Selby Wilson, M.D. Lond., M.R.C.P. Lond., D.P.H., to Mary Joyce Ayrton, M.A., M.B., Ch.B. Camb.

DEATHS.

EMRYS-ROBERTS.—On Jan. 15th, at Archer-road, Penarth, Edward Emrys-Roberts, M.D., Professor of Pathology, University of Wales, Cardiff, aged 45.
PHILIP.—On Jan. 15th, at Disraeli-road, Ealing, of heart failure, James Allan Philip, M.A., M.D., late of Boulogne-sur-Mer, aged 78.
REID.—On Jan. 15th, at Chur, Switzerland, Archibald Douglas Reid, K.B.E., C.M.G., aged 52. Beloved and only surviving son of Douglas A. Reid, M.D., J.P., 1, St. Augustine's Mansions, Westminster, S.W. 1, late of Tenby, S. Wales.
SIBBALD.—On Jan. 14th, at Crewkerne, Bernard Ian Graham Sibbald, M.B., aged 52 years.
THURSFIELD.—On Jan. 14th, Thomas William Thursfield, M.D., F.R.C.P., of Leamington, aged 84 years.
TURTON.—On Jan. 11th, James Turton, J.P., F.R.C.S., of 42, Norfolk-square, Brighton, aged 68 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

INSURANCE MEDICAL PRACTICE: A COMPARATIVE VIEW.

THE club doctor or Kassenarzt is passing through an anxious time in Germany. As our Berlin correspondent related last week, the radical changes in attendance on club members, forced on the doctors by the new Government, have caused a great upheaval. Medical opinion in Germany has pointed out as one man that the free-choice system of club practice is the only one likely to ensure careful attendance to club members, and popular opinion has supported this view. So far the doctors have been able to maintain their position of being unwilling to work under conditions which they regard as derogatory. Historically, it is interesting that, whereas in the drafting of the Insurance Acts free use was made of German precedents, Germany should now be turning with envious eyes to the present conditions of insurance medical service in this country.

In the *Medizinische Klinik* for Jan. 13th Dr. R. Güterbock makes a critical review of insurance against sickness and invalidity as it exists in this country. Its advantages he regards as too evident to require emphasis. The only drawback he finds in the provision of hospital treatment; this, he says, is closely related to the English plan of leaving their hospitals largely dependent on voluntary offerings, which results in the provision of a sufficient number of free beds in towns. But even in England, he adds, the arrangement is becoming intolerable and the medical profession is urgently demanding the provision of larger sums for hospitals and for the erection of maternities. Dr. Güterbock takes account of the relatively unfavourable position of the deposit contributors who, he believes, belong usually to the poorest of the poor—"tramps, drunkards, and skrimshankers." It is very hard on them that their sickness benefit should be limited by the sum which is paid into the fund, and for these, he says, new ways are being sought; for this category of humanity German insurance law makes no provision whatever. A further possible disadvantage Dr. Güterbock sees in the lack of death-money, to set against which there is the old-age pension, the unemployment benefit, and the better hospital provision. Such disadvantages as exist are entirely outweighed by the simplicity and economy produced by the pooling of sickness, invalidity, and unemployment benefits. In Germany no exact figures of the cost of administration have been made public; Dr. Güterbock quotes, but has been unable to check, the statement from an English source that in Germany administrative expenses amount to 70 per cent. He concludes his review by briefly referring to the dispute between the British Minister of Health and the doctors. The Minister, he said, based his proposed reduction in the capitation fee on the salary reduction of civil servants. The doctors' rejoinder would apply equally to German circumstances—viz., that the doctor draws no pension, that during holidays his income falls while his outgoings continue, that the running expenses of practice, of which the official knows nothing, continually rise. But the British Minister fully realised that insurance service must in any case be so paid as to ensure a sufficient supply of capable doctors. All parties in England—the Government, the societies, organised labour, public opinion—are clear that only by the voluntary efforts of a medical profession protected against material want can any system of State insurance be permanently maintained; that, in fact, by lowering the standard of living of the medical profession the insurance principle will collapse, and the general health of the people must suffer. This is Dr. Güterbock's final comment.

The position of the Kassenarzt has recently become so pitiable as to elicit some measure of public sympathy in Germany, as may be seen from a cartoon here reproduced from a recent issue of *Simplizissimus*. The legend runs:—

Left: Work so that you may pay regularly your club money.
Right: When you are ill, the miserably paid club doctor comes. . .

ne good feature of an otherwise painful situation is that ie quarrel with the clubs has united the medical profession Germany as it has never been united before.

COUNTY SCHEMES FOR THE PREVENTION OF TUBERCULOSIS:

THEIR ORGANISATION AND ADMINISTRATION.

At the Royal Institute of Public Health on Jan. 23rd r. G. Lissant Cox, central tuberculosis officer, Lancashire ounty Council, delivered a lecture on this subject, of which ie following is an abstract.

It must be remembered, said Dr. Cox, that all schemes nd measures dealing with tuberculosis should have pre-ention as the ultimate aim; it is more important that at tuberculosis dispensary patients be taught how to use aper handkerchiefs than that they should be supplied ith cod-liver oil and malt. Any thorough tuberculosis heme should be capable of dealing with: (1) pulmonary iberculosis in children and adults; (2) non-pulmonary iberculosis in children and adults; (3) tuberculosis in attle.

I do not propose to deal with tuberculosis in cattle, xcept to say that if public opinion would force on measures o reduce the 2 per cent. or thereabouts of cattle with tuber-ulosis of the *udder*, very many children would be saved om crippling disease, many from death, and much expendi-ure saved on treatment.

The Tuberculosis Officer and the County.

Given sufficient scope and material, the success of any cheme depends ultimately, of course, upon the man ppointed to work it. It is, I think, generally recognised hat counties or county boroughs large enough to be able o employ one or more whole-time tuberculosis officers how more efficient schemes and better results than places here only a part-time officer can be employed. There re two conceptions as to the main lines of a tuberculosis fficer's work. First, that he be a first-rate clinician, paid s such, and looked upon as a consultant by the doctors n general practice, but having administrative ability and public health outlook; and, secondly, that he be a part-ime tuberculosis specialist undertaking other public health ork (school medical duties, &c.).

The very great differences which exist in England between he size of different administrative units is a factor whose mportance is not infrequently forgotten, especially by ersons who elaborate theoretical schemes for the preven-ion and treatment of tuberculosis. I need only give nstances such as the administrative county of Lancaster, ontaining a population of 1¾ millions, and the counties of Iuntingdonshire with 55,000 of a population, and Rutland ith less than 20,000.

Dispensary Organisation.

The headquarters staff and intelligence department of he campaign against tuberculosis is at the present time ocated in the tuberculosis dispensary and works through he dispensary organisation. The dispensary organisation onsists of a tuberculosis officer, tuberculosis nurses or ealth visitors, the dispensary clerk or clerks, and, in addi-ion, a building. Its functions include: (1) Diagnosis of atients or contacts of patients, and determination as to orms of treatment; (2) supervision of home treatment, ncluding general hygienic precautions as to spread of nfection; (3) keeping of records and information of all kinds; (4) keeping in touch with the local care committee, nd, in county areas, with the local sanitary authorities.

All tuberculosis schemes consist of one or more such dispensary units. The size or number of these units will depend upon the size of the population of the county. The minimum number of population for a single whole-time tuberculosis specialist should be about 150,000. As a general rule, if the area contains less than this number, there is not enough tuberculosis work for one man, who in consequence must take on other work and cease to be a full-time tuberculosis officer. It must be remembered that a county area consists of a number of local sanitary areas, either rural districts, urban districts, or non-county boroughs, each of which has a separate sanitary administration—that is, each has a medical officer of health with a staff and a council to which he is responsible.

In Lancashire the population in the county area alone, excluding the county boroughs, is 1¾ millions. The dispensary units are five in number, and consist of an average population of 345,000, each area being under the charge of a consultant tuberculosis officer having a chief dispensary with an office, clerical staff, X ray room, laboratory, and throughout the unit two, three, or more branch dispensaries; and to assist the consultant tuberculosis officer there are in these large dispensary units one or more assistant tuberculosis officers, and in each unit six or eight tuberculosis nurses. This arrangement has up to the present worked very well. In spite of many of the local sanitary areas having populations varying from 20,000 to 45,000, it has been found quite easy to make arrangements with local medical officers of health whereby all visiting is done by county nurses, the initial reports on the homes being accepted by the local medical officers of health, so that no overlapping whatever occurs. This is a very important point in county administration.

If the tuberculosis officer is really to be a specialist, treated as a consultant by the general practitioners, he must have, in addition to natural ability, all modern aids to diagnosis, and no scheme is complete which does not include the provision of an X ray plant. This, to be of greatest use, must be in the chief dispensary and used by the consultant tuberculosis officer himself, as is done throughout Lancashire.

No tuberculosis scheme is complete without care work and care committees. The tuberculosis officer must act as medical adviser to prevent any overlapping as regards assistance to the patient from other agencies. Not the least important result of having care committees composed of representatives of local authorities, trade-unions, guilds of help, and others is the knowledge gained by these members of the real nature, extent, and aims of the county or borough work dealing with the prevention of tuberculosis. The five dispensary units in Lancashire have at present 15 care committees, and the amount or value of goods distributed last year was £1500.

Institutional Accommodation.

The provision of institutional treatment which is necessary in every complete and efficient tuberculosis scheme will include (*a*) sanatoriums for children and adults (pulmonary tuberculosis) for early and intermediate cases and observation cases; (*b*) pulmonary hospitals for the isolation and treatment of chronic or advanced cases, or cases acutely ill, as near to their homes as possible; (*c*) arrangements with general hospitals and infirmaries and convalescent homes for surgical cases, children and adults; (*d*) special hospitals for children suffering from non-pulmonary tuberculosis; (*e*) tuberculosis settlement. It will be easily seen from this list of different kinds of institutional treatment that the larger the area, the better chance there will be of financial arrangements to carry them out. With regard to children, provided that nothing is done as regards tuberculous cattle, it would appear that about one bed per 19,000 of the total population is required for pulmonary cases, and one bed per 12,000 of the total population for non-pulmonary cases.

Sanatorium Treatment.

Given reasonably early cases for treatment, and an institution with a whole-time and capable man at its head, sanatorium treatment still holds the field. In Lancashire, of 3950 early and intermediate cases of whom 2270 went to a sanatorium and 1680 did not, the deaths at the end of 1922 among those who entered upon treatment during the five years 1914–18 were as follows: (*a*) Of patients with "negative" or "absent" sputum at the end of 1922, 16 per cent. of sanatorium cases and 42·6 per cent. of non-sanatorium cases had died: (*b*) of patients with "positive" sputum at the end of 1922, 66·2 per cent. of sanatorium cases and 84·8 per cent. of non-sanatorium cases had died. As regards prolongation of life, these results favour sanatorium treatment. Even if they were less favourable, it must never be forgotten that from the more important side of the prevention of the disease a stay in a sanatorium has, in the main, a definite educational result on the patient, his family, and his friends.

Cost of a Tuberculosis Scheme.

All tuberculosis schemes are financed partly from the rates and partly by grants of 50 per cent. of the net approved expenditure by the Ministry of Health, which also makes certain other payments for specific purposes, whilst the Ministry of Pensions contributes for the present towards the cost of treatment of tuberculosis pensioners. In Lancashire a penny in the pound on the rateable value brings in £36,000. Our scheme costs about one penny halfpenny (1½*d.*) as far as the rates are concerned, so that the total gross expenditure is about fourpence in the pound on the rateable value—or to put it another way, about £150,000 per annum for a population of 1¾ millions.

THE TRAINING OF AMERICAN NAVAL HOSPITAL CORPS.

THE ranks of the officers of the Medical Corps are acting assistant surgeon, assistant surgeon, and assistant dental surgeon, who all "have the rank of lieutenant (junior grade)"; passed assistant surgeon, passed assistant dental

surgeon, lieutenant; surgeon or dental surgeon, lieutenant commander; medical inspector, commander; and medical director, captain or rear-admiral. Above all these is the "Chief of the Bureau of Medicine and Surgery, with the rank of rear-admiral, title of Surgeon-General, and pay and allowances of major-general in the army." In the Nurse Corps are nurses, chief nurses, and superintendents. The "Hospital Corpsman" begins as a hospital apprentice, 2nd class (probably ordinary seaman), who does not appear to go to sea until he is advanced to 1st class; in time he becomes a petty officer with the title of pharmacist's mate, 3rd, 2nd, or 1st class; later he may be promoted chief pharmacist's mate, and then to warrant rank as pharmacist, and after six years more to chief pharmacist.

These men are all to be trained by means of a recently published handbook [1] which explains the navy to them, telling them how it is organised by departments, and lets the intelligent and curious recruit understand what is happening around him and why; besides it sketches for him the history of the Hospital Corps, and gives him a list of all the officers who have presided over the medical department, from William Paul Crillon Barton in 1842, to Edward Rhodes Stitt to-day; it tells him where the money comes from to keep the naval hospitals going, and what establishments there will be to receive him if, by ill luck, he is invalided out of the Service—all very interesting. Primarily this book is for the education of the recruit, but the needs of the petty officer, away by himself with no medical officer to rely on, in a small craft or at a shore station, has been ever in the minds of the compilers, and thus are explained some surprising directions. For example, if appendicitis is suspected the "corpsman" is advised to "make a white count if possible," and the treatment of Vincent's angina with Fowler's solution or chromic acid, as recommended, would appear an absurd and risky suggestion to be put before any chance orderly. There are the usual sections on anatomy (the picture of the skeleton is credited to the manual of the Royal Naval Sick Berth Staff, and the bones of the carpus are given in both the ordinary and the Berne nomenclature); physiology, first aid, including dental first aid and temporary stoppings, bacteriology, blood and urine examinations, diseases, including human parasites, with very detailed studies of the exanthemata, field sanitation, marches, X rays, drug addiction, massage and physiotherapy, chemical warfare, statistics, death, and embalming. There is a section on nursing by members of the nurse corps, with admirable detail for making beds. Chief pharmacists provide chapters on chemistry, pharmacy, materia medica, clerical work (with most useful lists of forms required on occasion, as when an officer wants leave or a deserter returns on board), administration of naval hospitals, foods, and dietaries—all most excellent.

The section on foods is particularly striking with its numerous tables to assist the hospital commissary (quartermaster, as we might say, or steward), a chief pharmacist, to construct from day to day and a week ahead, the diets, which are ordered to be varied and pleasant to eye and palate, and to give to each man 3563 calories per day. The lists of the 225 possible rations from which to choose are complete and detailed, and include, for example, "Angel cake; one piece, $1\frac{1}{4}'' \times 2'' \times 2\frac{1}{2}''$; 1·3 oz.; 100 calories. Pineapple, canned, sliced; one slice and three tablespoonfuls juice; 2·3 oz.; 100 calories. Lamb chops, braised, two chops; meat portion, $2'' \times 2'' \times \frac{1}{2}''$; 200 calories." It is always held in the merchant service that American sailors are very well fed; it seems that their bluejackets do pretty well too. There should have been greater care in revision; nerve fibrils do not "enervate" muscles (p. 65); "straight jacket" (p. 137), and "Colle's" fracture (pp. 81, 82, and in the index) are further examples. But in spite of small blemishes it is a wonderfully good book, and the various articles reflect credit on their authors. The "corpsmen" for whom it was thought expedient to have this book written should become valuable men; certainly the articles contributed by their chief warrant officers do great credit to the education they have been given during their service in the Hospital Corps of the United States Navy.

THE BRIGHTON INTERCEPTING SEWER.

WHEN the Brighton intercepting sewer was constructed—the work was begun in January, 1871, and completed in June, 1874—the population of the district served by it (the towns of Brighton and Hove) was, in round figures, 100,000. The population of the district is now over 190,000, and the time has come when attention must be given to the sewer, and the corporation is now seeking a provisional order that it may have power to cope with the demands that are being made upon the sewer to-day. By the present plan, as originally designed and constructed by Mr. (afterwards Sir) John Hawkshaw, the outfall into the sea at Portobello, some miles east of Brighton, is completely tide-locked for six and a half hours during each 24 hours, and more or less tide-locked for 12 hours per day. This has resulted in the sewer tank being charged unduly and the storage for storm water reduced. It is now proposed to reconstruct the outfall end of the sewer, and put down a new outfall from the point where the original sewer ended, and to have four 48 in. discharge pipes instead of three, and to carry the outfall 100 yards further out to sea. It is also proposed to fix three pumps, each with a capacity of 900 cubic feet per minute, two to be always working and the third as a standby, thus providing for a continual discharge for 24 hours per day, instead of the present limited discharge, and providing for an even flow of sewage as against the present storage for some hours. At the Ministry of Health inquiry held on Jan. 15th tribute was paid to the work of Sir John Hawkshaw in constructing the sewer, the cost of which was £100,000, the last repayment of the loans falling due during next year. This repayment has been a long and expensive process, but it has been warranted by the town's clean bill of health; so also doubtless will be the expenditure of £120,000 which is now being sought to provide not only for the needs of the moment, but for a population of 300,000.

THE PANEL SERVICE.

To the Editor of THE LANCET.

SIR,—Apropos of the recent case against two Lancashire doctors who were fined £1000 between them for breach of rules, would it not be reasonable for the panel practitioners to know exactly what are the powers of the Minister of Health (from whose decision there is no appeal) as regards the infliction and extreme range of penalties? The patients are informed on their cards (which they seldom even read) of the maximum penalties which can be inflicted on them—one never reads in the daily press of a patient being punished. Why not inform the practitioners? We have read of the £1000 fine; what is to prevent us reading of a £10,000 fine, imprisonment, or such other punishment? What would happen if a panel practitioner, whose panel was worth £200 per annum, were fined £1000 and he promptly gave three months' notice and resigned? Could any legal proceedings be taken against him?

I am, Sir, yours faithfully,

Jan. 12th, 1924. "PANEL DOCTOR."

SPUTUM TREATMENT OF WHOOPING-COUGH.

Prof. R. Kraus,[1] of Vienna, who was formerly in charge of the Serum Institute at Butantan, Sao Paulo, describes his method of treatment of whooping-cough, which has been employed in more than a thousand cases in hospital and private practice in the Argentine, Uruguay, and Brazil. The method consists in the subcutaneous injection of "antitossin," which is a preparation of the sputum of whooping-cough patients obtained during the first few days of the paroxysmal stage. The sputum is not employed until it has been found to be free from tubercle bacilli and other organisms by aerobic and anaerobic tests and by animal inoculation. The results of treatment were that the injections were followed by disappearance of vomiting, diminution in the number of the attacks, and a change in their character, the cough first becoming catarrhal and then ceasing altogether. Early treatment gives the best results. No bad effects were observed apart from transient local tenderness and infiltration and a rise of temperature which fell to normal in 24 hours. The dosage ranged from 1–5 c.cm., but as a general rule it was best to begin with 2 c.cm. and to repeat the injections every two or three days. An improvement was often seen after one or two injections, while in other cases three or four injections had to be given before any change was noticed, and some did not react at all. In the last group of cases successful results were obtained by inoculation of the patient's own sputum. The nature of the active agent in the preparation has not yet been determined, but the treatment is probably a form of protein therapy combined with some specific agent, as treatment of pertussis with the sputum of healthy persons or asthmatics had no effect.

[1] Wiener medizinische Wochenschrift, Nov. 24th. 1923.

T. N. H.—We have never heard of poisoning by CO initiating permanent and serious blood changes. It is occasionally followed by pneumonia, presumably broncho-pneumonia, just as it sometimes leads to multiple cerebral hæmorrhages. Harmful after-effects are certainly rare. Practically speaking, carbon monoxide is poisonous only because it combines with hæmoglobin, the shortage in oxygen-supply when not excessive being completely recoverable.

Present Position OF THE TREATMENT OF HYPERTROPHIC PYLORIC STENOSIS.[1]

F. JOHN POYNTON, M.D., F.R.C.P. LOND.,
PHYSICIAN TO THE UNIVERSITY COLLEGE HOSPITAL AND THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET;

T. TWISTINGTON HIGGINS, F.R.C.S. ENG.,
SURGEON TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET, AND THE ROYAL NORTHERN HOSPITAL;

AND

J. M. BRYDSON, M.S., B.S. DURH.,
LATE HOUSE SURGEON, HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET.

WE feel that there may be some danger that the ject of pyloric stenosis in infancy may seem thread- re, for much has been written upon it of late. In te of this, however, there apparently still remains certainty and difference of opinion upon certain dinal points which are of interest to physicians, geons, and pathologists, and we think that on this ount this would be a subject in harmony with that hly prized feature of this society, its general broad tlook upon medicine. We have ourselves arrived a definite conclusion upon the treatment of the ease, and wish to place our views before the society, ough in no arrogant spirit and with no claim to ginality. This conclusion we are prepared to dify if further study throws clearer light on the use of pyloric stenosis, but in the present phase of r knowledge we believe it to offer the best results. can be expressed in one sentence. *When once the agnosis has been made, operate at the earliest oppor- nity.* This is a definite statement, and the object of r communication is to put forward our reasons based on the exact details of our procedure and our results. Although the physician in these cases has to work nd in hand with the surgeon, the essential step in e successful result is the surgical procedure. At the tset one of us (F. J. P.) would like to put his own titudes to the treatment of pyloric stenosis over a riod of 20 years. Brought up, when once he learned recognise this condition, to treat it on medical lines, soon became convinced that for some cases this was peless. When he came in charge of wards he had ached the stage of seeing the necessity for ascer- ning which cases required operation, and then opted the attitude of giving a trial to medical treat- nt in all clear cases before approaching the surgeon. w when the diagnosis is made he at once advises operation—a position largely due to the debt which ysicians owe to such pioneers as Cautley and Clinton nt, Still, Burghard and Rammstedt. This attitude idently demands the necessity for making a sure agnosis, and leads to a cardinal point.

The classical symptoms of pyloric stenosis are, as we ow, projectile vomiting, visible peristalsis, tumour, d constipation. Active visible peristalsis is valuable, t for us the tumour is of the first importance. We cognise there is a decided difference of opinion upon e frequency of its detection and therefore upon its agnostic value. Nevertheless, our conviction is that we do not lay the greatest stress upon the tumour, shall find in the future many cases operated upon at are not really suffering from pyloric stenosis. ne of us (F. J. P.) inquired one day of a "nutritional ecialist" what criterion he took as a guide in spected cases, and was told loss of weight, but with is he did not agree.

[1] A paper read before the Medical Society of London, n. 28th, 1924.

EXAMINATION FOR THE TUMOUR.

Our experience has been that so far we have failed to find the tumour in only one case, though we have had difficulties with a few. In that single case our house physician had felt the tumour on one occasion. We have had no case in which death has occurred and an undetected tumour been discovered, and no case in which, when a tumour was felt, it was found non-existent at the operation. Having spoken so strongly upon this point we feel bound to give in detail our method of examination.

To relax our own muscles we sit beside the cot on the left side of the infant. The nurse gives a feed of milk or glucose water, and the left hand thoroughly warmed (a most necessary precaution) is laid flat over the epigastrium and kept motionless until it becomes a part of the abdominal wall. The edge of the liver, which is always palpable, is defined by the upper border of the index finger, and then the pylorus traced with the pads of the fingers used with the lightest possible pressure. The difficult tumours are those lying high up under the edge of the liver, but they can usually be detected on inspiration by their harder consistence. Another difficult one is the tumour that relaxes quickly. Some feel like the tip of the nose, some run transversely into the stomach wall, and some lie low down further to the right than usual toward the renal region. When we are sure that we feel the tumour, we only wait for the child to recover from any collapse due to the journey to the hospital before commencing the procedures for operation. We do not, as a rule, give bismuth meals, because our experience has been that they may do harm to an infant who has no reserve power, and they do not in ordinary cases tell us more than we can discover by clinical examination.

It may be asked, Do you never meet with a case in which you are not sure that there is a tumour, and yet from other symptoms you believe it to be a case of stenosis? Our answer is that, so far, in our series we have met with some doubtful cases, but with the one exception already mentioned, when we have not felt a tumour there has not been an operation, and these cases have either recovered or, if they have died, have not been cases of pyloric stenosis. Possibly we have been unusually fortunate, and one of us has met with two cases (not in our joint series) in which there was no tumour felt, but in these the remarkable peristalsis in association with the other symptoms led to a right decision. The great hindrance to a successful result has been, in our experience, the *duration* of the symptoms, and we shall later support this statement in an analysis of our statistics.

A strong infant with a long history of starvation is more likely to succumb than a weakly one with a recent history. One group to which further allusion will be made is that in which in the chronic disease there supervenes an acute exacerbation of vomiting with prostration and even fever. In such cases we at once press on operation. In practical terms we consider no case too ill for operation, for it is our experience that those that seem the most unfavourable may make easy recoveries, while the more promising ones may prove to be the most anxious. We look upon it, however, as essential to have a most careful plan of procedure, and shall give this in detail, not because we believe it to be infallible or beyond improvement, but because it has been very successful, was gradually evolved by sheer experience, and may be helpful to any who have not had the same opportunities. It has been evolved from the difficulties we have encountered and which we now enumerate.

DIFFICULTIES.

(1) Extreme illness and shock; (2) accidents during operation; (3) neglect of precautions in after care—viz., to avoid chill, to guard against high fever, and shock; (4) enteritis; (5) marasmus, in cases with a long history. Lastly, the physician is not anxious himself to perish from "case stenosis" as the result of the inroads of surgeons upon his territory; and if all the elaborate details concerned with the operation

were undertaken, success might, it was thought, follow without any surgical help. This was tried on a breast- and hand-fed infant respectively. In each case it was found that when the diet was raised above the starvation level the symptoms recurred, and operation was called for. One baby survived, the other died unable to endure the second period of partial starvation involved. These two cases were not considered to be fair to the surgeons, and they are not included in the series; but apart from them there has been no mutilation of our statistics.

In discussing the operative procedure adopted in these cases, and in presenting our results, we desire to make full acknowledgment of our indebtedness to those other surgeons, especially Rammstedt and Burghard, who have helped to improve the technique and have added to the literature of this subject in recent years. All our cases have been operated on by the "Rammstedt" method of transperitoneal section of the pyloric sphincter. We are satisfied that this method offers the quickest and safest means of relieving the stenosis. We will now describe the operation in detail:—

PRE-OPERATIVE TREATMENT.

(*a*) *Gastric Lavage.*—It is most important to have the stomach as empty and as clean as possible at the time of operation. A distended stomach makes for operative difficulties, while the passage of stagnant stomach contents into the intestine, immediately the pyloric stricture is relieved, is most undesirable. A short course of gastric lavage is therefore an essential preliminary, especially in long-standing cases with very dirty stomach contents. The final wash out is done one hour before operation.

(*b*) *To Combat Shock.*—Subcutaneous infusions of saline with glucose (2 per cent.) are administered usually twice, (1) 12 hours, (2) two hours before operation, 1½ oz. being run into each axilla. The baby's limbs are bandaged in cotton-wool, and the trunk warmly wrapped. The operating room is specially heated (75° F.).

(*c*) The last feed is given four hours before the operation.

(*d*) No preliminary hypodermic injection is used.

ANÆSTHETIC.

Ether and chloroform are contra-indicated by the grave danger of acidosis in these starved infants. We now use gas and oxygen in all cases. With this we have frequently combined local infiltration of the abdominal wall (skin and rectus sheath) with novocaine and adrenalin (novocaine 2 per cent., adrenalin sol. 1 in 1000, 5 minims to 1 oz.) with the object of diminishing shock and rendering the closure of the peritoneum more easy. Five of the worst cases in the total series were successfully operated upon under the local infiltration alone. We believe it to be a valuable addition to gas and oxygen in collapsed infants.

Position.—The baby is laid on a well-protected hot-water bottle, so as to throw the epigastrium into prominence.

OPERATION.

The abdomen is opened above the umbilicus to the right of the middle line by incising the rectus sheath and reflecting the muscle outwards. The stomach is picked up from beneath the liver edge and the pylorus delivered. Escape of intestine is prevented by a narrow "pack" tucked into the lower angle of the wound, and as little of the stomach as is necessary is brought out of the abdominal cavity. We employ the following method in dividing the sphincter: The operator fixes the pylorus with his left thumb and forefinger, while the assistant gently grasps the stomach; the "avascular" line on the anterior surface of the pylorus, close to its upper border, is identified. Occasionally this line may be invaded by a vascular twig, and we always attempt to circumvent such a little vessel if met with. With a clean scalpel the incision in the pylorus is begun, dividing the peritoneum and just entering the muscle layer. The muscle section is completed by using a pair of closed scissors as a blunt knife. This instrument divides the muscle quite easily and cleanly, and cannot injure the mucous membrane, as the latter bulges into the gap. The section must, of course, completely divide the pylorus, and special attention is always given to both ends of the incision with the object of ensuring this. Having completed the section, the cut edges of the sphincter are undermined, and the gap widened so as to ensure that the mucous membrane will bulge and herniate well up into the gap.

The pylorus is now carefully inspected for any bleeding-point. Occasionally a small vessel may ooze in the subperitoneal or in the submucous coat. Usually a pinch with forceps suffices to stop this. If necessary it may be underrun with a fine needle and catgut, or a muscle graft taken from the rectus abdominis may be applied. In our experience oozing of this type is rare. We believe that blunt section of the pylorus and thorough undermining by the method described are most important details in minimising the possibilities of hæmorrhage. In a personal experience to date of 65 cases, one of us (T. T. H.) has very rarely been delayed by a bleeding-point at the time of operation, and there has been no fatality from hæmorrhage in his practice. The pylorus having been returned to the abdominal cavity, the abdomen is closed in layers with fine catgut.

The peritoneal layer is sometimes troublesome, especially if the child is not taking the anæsthetic well. The omentum, aptly described by Mr. F. F. Burghard as "seaweed," floats up into the wound, and may make this the only really difficult step of the operation. The incision is always closed from below upwards, as by this means full use is made of the liver as a retractor in putting in the final stitches. The skin incision is closed by a single subcutaneous stitch of silk-worm gut. The wound is sealed with Whitehead's varnish and a small dressing and bandage are applied. The infant is rapidly enveloped in a warm blanket and carried back to bed. The operation lasts about ten minutes in the average case. Speed is certainly valuable, but in the words of Sir Berkeley Moynihan it should be the "daughter of experience and not the parent of disaster." It should never replace gentleness and delicacy of handling, which are first essentials.

POST-OPERATIVE TREATMENT.

The immediate post-operative concern is to keep the infant warm. If the condition is poor the lips are rubbed with brandy, and oxygen is administered occasionally. The temperature is recorded hourly (Fig. 1), and if it rises above 102° F. an ice-bag is put on the baby's head. This controls the development of post-operative hyperpyrexia, which is an occasional complication. Further subcutaneous saline is administered if necessary, but must be used with discretion for fear of "waterlogging" the lungs. In the case of hospital patients, we advocate early discharge to their homes.

Feeding.—We append our exact methods of post-operative feeding (*a*) in a breast-fed infant, and (*b*) in a bottle-fed infant.

Feeding of Pyloric Stenosis After Operation.

(A) *Breast-feeding.*

Operation 10.30 A.M., return to ward 11 A.M., milk drawn from mother four hours after.

First day: 3 P.M. to 8 P.M., ℥i. hourly; 9 P.M. and 10 P.M. ℥ii; 11 P.M. and 12 P.M., ℥iii.

Second day: 1 A.M. and 2 A.M., ℥iii.; 3 A.M. and 5 A.M., ℥iv.; 7 A.M. and 9 A.M., ℥vi.; 11 A.M., 1 P.M., and 3 P.M., ℥i. (to breast for three minutes, time varies); 5 P.M. ℥iss. (to breast for five to seven minutes); 7.30 P.M., ℥iss. Continue 2½-hourly for 12 hours.

Third day: 7.30 A.M. (3-hourly for 12 hours), breast five to seven minutes; 7.30 P.M., 3-hourly, breast for ½ hour or 20 minutes.

These babies are weighed before and after feeds for first few days.

(B) *Bottle-feeding. A Reliable Skimmed Dried Milk.*

Operation 10.30 A.M., return to ward 11 A.M., four hours er commence feeding.

First day: 3 P.M. to 8 P.M., ℥i. hourly; 9 P.M. and 10 P.M., i.; 11 P.M. to 1 A.M., ℥iii. hourly.

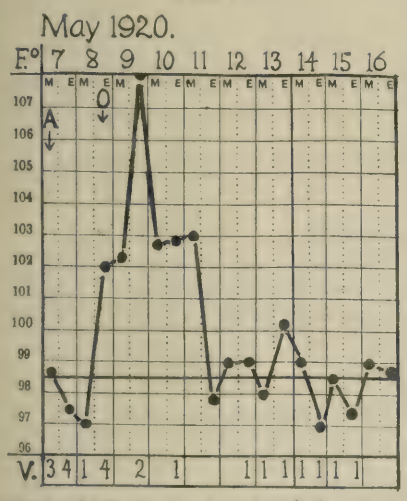
Second day: 2 A.M., ℥iii.; 3 A.M. and 5 A.M., ℥iv.; A.M. and 9 A.M., ℥vi.; 11 A.M., 1 P.M., and 3 P.M., ℥i.; .M. and 7.30 P.M., ℥i. ℥ii. Continue 2½-hourly for 12 hours.

Third day: (Dried milk (half cream), ℥i.–℥i.), 7.30 A.M., s., 3-hourly for 12 hours; 7.30 P.M., ℥ii. 3-hourly. Increase ℥iiss. or ℥iii., according to age.

RESULTS.

In presenting our results we desire to make it clear at our cases have been in no way selected. Certain agnosis of true hypertrophic stenosis has been the dy criterion. Our lists, therefore, include desperate d acute cases. Certain acute exacerbations of

FIG. 1.



Pen perature chart, case of congenital pyloric stenosis. ustrating hyperpyrexia immediately after operation. V = Times of vomiting.

mptoms have been alluded to as forming no contra- dication to operation. Indeed, under certain cumstances such manifestations, in our judgment, dicate that surgical intervention is urgent.

A case may be primarily acute, or acute symptoms ay supervene in a more chronic case. In the imarily acute case the march of events is excessively pid. All the symptoms from the outset are very vere. Vomiting is copious and incessant. Within very few days of the actual onset the infant becomes armingly collapsed. Such cases are surgical emer ncies. The pylorus is found small and stony-hard. spite of the collapsed condition these children do ell. In some other cases, which have presented a ieter course, acute exacerbations occur, associated th severe outbursts of vomiting, and frequently th rise of temperature. In such cases the temptation to postpone operation until the acute symptoms ne, but there is more than a chance that the baby ll die before they do so. We always regard these ses as urgent also. We have on several occasions erated on a child whose temperature has been up 102° F. or more, and the results have been most atifying.

The total number of our joint series, with which are mainly concerned in this present paper, is . Of these, 16 have been cured, four have died. is gives us a percentage of recoveries of 80 per nt., and a mortality-rate of 20 per cent. Since ugust, 1921 (i.e., during the last two and a half ars) we have lost only two cases out of a total of 16.

e wish to refer briefly to the fatalities:—

1. Our first case, in July, 1920, was a bottle-fed infant ed 9 weeks, with a complete harelip and cleft palate, in om the symptoms had existed for 60 days. The operation as performed under local anæsthetic, with a small amount ether. The infant did well until the third day, when it llapsed and died. Post mortem the pylorus was patent, and there was no bleeding. This was a very wasted infant with a severe associated facial deformity. Note the long duration (60 days).

2. Our fourth case, in August, 1921, was a bottle-fed baby aged 10 weeks, in whom the symptoms had been present for 14 days. The infant was extremely emaciated and weighed only 6 lb. The operation was performed under N_2O and oxygen. The baby never really rallied, and died after 18 hours. Post mortem the pylorus was patent and there was no bleeding.

3. Our eighth case, in June, 1922, was a bottle-fed infant aged 6 weeks who had vomited since birth. The diagnosis was in doubt in this case, and in consequence there was some delay before operating. The pylorus was found high up under the liver. Death occurred from shock 24 hours after operation. Post mortem the pylorus was patent, and there was no bleeding. The baby was found to have a double hydronephrosis of advanced degree.

4. Our eighteenth case, in June, 1923, was a twin baby aged 15 weeks, in whom the symptoms had been present practically from birth—i.e., the duration was certainly over 100 days. The infant's condition was very poor. The operation was performed under N_2O and oxygen. The pylorus was enormously thickened, as was the whole stomach wall. All went well until the third day, when an infective enteritis developed. To this was superadded on the fifth day an ulcerative condition of the mouth, pharynx, and larynx; swabs showed no Klebs-Loeffler bacillus, but some "suspicious bacilli." Death occurred later on the fifth day. Post mortem the pylorus was patent, and there was no bleeding. The intestines showed a mild enteritis. The larynx and œsophagus as far as the cardiac orifice were covered by a grey membrane (further swabs showed no Klebs-Loeffler bacillus). Death in this case must be ascribed to an intercurrent diphtheroid infection. We would emphasise the long duration—100 days. Such an infant maintains its hold on life by the slenderest of threads.

We submit that fatalities in four such cases as those related can hardly be said to shake one's confidence in the value of the operation. But it may be said that our joint series of 20 cases is too small, and we wish therefore to take this opportunity of presenting the results of a much larger series; this comprises the first 55 cases which have been operated upon by one of us (T. T. H.) during the last four years. This total number includes the previously quoted 20 cases. In all, the operative details have been identical, and the post-operative feeding has only differed in minor details according to the predilections of individual physicians. We are indebted to our medical colleagues for permission to quote these cases.

FIG. 2.

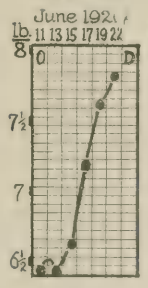


FIG. 3.

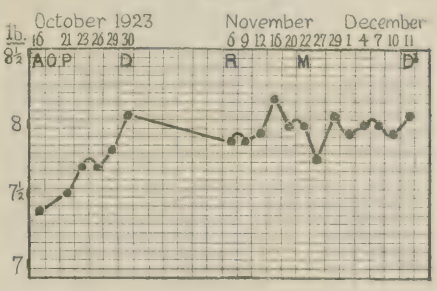

FIG. 2.—Weight chart from a case of pyloric stenosis: duration 14 days. Illustrating rapid gain in weight after operation. O = Operation. D = Discharge.

FIG. 3.—Weight chart of a case of pyloric stenosis in which the symptoms had existed for 60 days, illustrating the slow gain in weight after operation.

A = On admission. O = Operation. D = Discharged. R = Readmitted. M = Humanised milk 3 oz. every 2½ hours. D¹ = Discharged improving gradually.

Of the 55 cases, 41 were cured and 14 died. The total recovery-rate has therefore been 71 per cent., and the total mortality-rate 29 per cent.

It is gratifying to our efforts to note the improvement in the results by years. Thus, in 1920 and 1921, in a total of 20 cases, the mortality was just under 45 per cent. In 1922 and 1923, in a total of 35 cases, the mortality was just under 15 per cent.

What are the factors which influence the results of the operative treatment of pyloric stenosis? We are

convinced that there is only one of paramount importance—duration of symptoms. Those cases in which early diagnosis is followed by prompt operation very rarely give us any anxiety.

The "Rammstedt" operation, if carried out as we have described, has few risks for the infant in fair condition. In such there is no shock. There need be no hæmorrhage or other surgical complications. The subsequent progress is rapid and there is no prolonged period of anxiety (Fig. 2).

All the troubles arise from delay, which fosters disaster in two ways: (1) The infant's general condition becomes progressively depressed, so that the actual operation risk from shock becomes correspondingly increased. (2) The infant's intestinal functions become progressively atrophied from disuse. Recuperation of digestive power must be correspondingly prolonged, while susceptibility to infections is increased. Hence the tragedies of "marasmus" and "enteritis," which account for half the deaths in this series.

The influence of this factor of time is clearly shown in our cases. We have arranged them in groups for the purpose, estimating the duration of the disease from the first onset of symptoms to the dates of operation. We have made three groups: (1) Duration 50 or more days, (2) duration 25–50 days, (3) duration under 25 days.

In group (1) (duration 50 or more days), total 11 cases. Result: Cured 4, died 7. Mortality-rate, 63·6 per cent.

In Group (2) (duration 25–50 days), total 13 cases. Result: Cured 8, died 5. Mortality-rate, 38·5 per cent.

In Group (3) (duration under 25 days), total 31 cases. Result: Cured 29, died 2. Mortality-rate, 6·4 per cent.

Of the total 14 deaths: Seven occurred within 48 hours of operation, and were due to post-operative collapse, seven occurred later at varying periods up to one month from infective enteritis or marasmus. All were examined post mortem, and in no case was there any perforation or undue hæmorrhage as a result of the pyloric incision.

But it is not only to the fatalities that we would point for evidence of the ill-effects of delay. The cases in Groups (1) and (2), which recover, do so reluctantly (Fig. 3). Convalescence is slow and anxious. Often diarrhœa occurs, which is sometimes severe. Altogether, in our experience, it is beyond question that the cases of long standing are in a category by themselves in point of seriousness.

CONCLUSIONS.

1. That in the present state of our knowledge (or ignorance) of the pathology of pyloric stenosis, operation offers the most speedy and certain cure of the disease.
2. That the operation of choice is Rammstedt's.
3. That the best results are obtained when the operation is performed at the earliest possible moment after the onset of the symptoms.
4. That the only absolute diagnostic sign is the feeling of the pyloric tumour, without this sign having been elicited operation is only justified in rare instances.
5. That in a breast-fed infant, where symptoms and signs develop suggestive of pyloric stenosis, the infant should not be weaned until a definite or negative diagnosis can be made, because experience has shown that feeding with breast milk is of great assistance to recovery.

THE Memorial Roll of the Royal Army Medical Corps, designed by Mr. Graily Hewitt, will be exhibited in Room 72 of the Victoria and Albert Museum (Department of Engravings, Illustration and Design) from Feb. 1st to 29th.

A RECEPTION will be held at the Royal Sanitary Institute, 90, Buckingham Palace-road, London, S.W., on Tuesday, Feb. 5th, at 5 P.M., to meet medical officers visiting this country under the auspices of the Health Organisation of the League of Nations.

NEW METHODS FOR THE STUDY OF THE PATHOLOGY AND TREATMENT OF TUBERCULOUS DISEASE.

BY SIR ALMROTH E. WRIGHT, M.D. DUB., F.R.S.

(With Coloured Plate.)

BEFORE any substantial improvements can be made in the treatment of tuberculous infection two things must be done. We must extend our immunological knowledge so as to discern what is lacking in the patient, and what requires to be done for him. And when we have in the light of such knowledge selected our treatment we must use sure means for discovering whether our therapeutic procedures fulfil their purpose. We must part company with those who overleap by a *saltus empiricus* intermediate events, and undertake to adjudicate by far-off indirect and often ambiguous clinical results; and we must set ourselves instead to follow out step by step, using laboratory methods, the train of effects produced by treatment—adhering doggedly to the *passus scientificus tutus*.

Here, as in all other infections, the proper way to begin will be to find out whether the infective agent can cultivate itself in the blood, in the blood fluids, and in the blood fluids in the presence of leucocytes. In previous papers [1] dealing with staphylococcic and streptococcic infections a general technique for these purposes has been described. That technique with certain changes can, as will be seen, be employed also in researches on the tubercle bacillus.

Hæmoculture in Slide Cells and Capillary Tubes.

The method consists in implanting graduated dilutions of a bacterial culture into the blood, and then filling this implanted blood into capillary tubes, or into slide cells. These last (vide loc. cit.) are shallow cells made from ordinary microscopic slides held apart and subdivided into compartments by strips of paper of standard thickness. Where staphylococci are

Descriptions of Illustrations on Coloured Plate.

FIG. I.—Normal blood implanted with a heavily centrifuged suspension of tubercle bacilli and incubated for nine days on a slide-cell. Marginal portion of the clot. The hæmoglobin has here been dissolved out from the red corpuscles by water, and the preparation has been stained by carbol fuchsin, followed by methylene-blue. The more copious tubercle growth at the inferior margin is related to the blood-clot having along this edge been in contact with air. Here, as also in the specimens depicted in Figs. III., IV., and VII., practically all the polynuclear and many of the large mononuclear leucocytes have emigrated to the walls, and only the small lymphocytes remain behind in the clot.

FIG. II.—Capillary tubercle-implanted plasma-clot. The preparation was obtained by implanting normal plasma with a centrifuged suspension of tubercle bacilli, by drawing this up into the stem of a capillary pipette, and incubating for four days. The clot was then simply blown out, dried on a slide, and stained with carbol fuchsin. The illustration shows a portion near the end of the clot where the microbes would have access to oxygen.

FIG. III.—Portion of a slide-cell clot from normal blood lightly implanted with tubercle and then incubated for 24 hours. Shows the aggregation of mononuclear leucocytes round a clump of tubercle bacilli.

FIG. IV.—Portion of a slide-cell clot similarly implanted and incubated for 48 hours. The specimen shows commencing "cavernation" round an agglomeration of leucocytes which are centred upon a group of tubercle bacilli.

FIG. V.—Portion of a capillary plasma-clot which was lightly implanted with tubercle bacilli. This was lodged in an "unlined" portion of a capillary stem and was then incubated for three days. The tubercle bacilli are here growing out unrestrained.

FIG. VI.—Another portion of the same clot which was lodged in a leucocyte-lined portion of the capillary stem. The leucocytes have here migrated from the walls on to the plasma-clot. Associated with this "admigration" there is a notable restriction of the tubercle culture.

FIG. VI.

nplanted into human blood the survivors grow out ito colonies which show up as bleached foci encircled y broad purple rings. In the blood of rabbits each aphylococcus colony is surrounded by a broad halo f hæmolysis. Again, in human blood colonies of emolytic streptococci may be ringed round with eas of hæmolysis. When tubercle bacilli are incuated in human blood the hæmoglobin of the red rpuscles is unaffected. We cannot, therefore, s in the case of staphylococci and streptococci, tell y simple inspection whether a culture has been btained.

To decide that we must dissolve out the hæmoglobin om the clot, and then stain and examine under the icroscope. In the case of slide cells we prise the slides sunder under water, add a little acetic acid or saponin, nd then, when hæmolysis is complete, transfer our in slabs of clot, which now look exactly like icroscopic sections, to clean slides. We then fix them the glass by drying in an incubator, and stain with rbol fuchsin, counter-staining with methylene-blue. lood-clots from capillary tubes—we may conveniently ll these *capillary clots*—are treated in exactly the me way. When tubercle-implanted blood-clots thus repared are microscopically examined—incubated eing compared with unincubated specimens—it is stantly seen that the tubercle bacillus grows out the blood. Even after so short a time as 24 hours ne single microbes which were implanted and which ersist as such in the unincubated clots have in ncubated clots grown out into groups of 2 to 5. fter 48 hours the clumps of tubercle bacilli are fficiently large to be easily visible under the low ower (magnification of approximately I × 100). n idea as to how vigorously the tubercle bacillus rows in blood can be obtained from Figs. I. and II. ig. I. represents a portion from the edge of a slide ell clot where (owing to the containing compartment aving here been only incompletely filled with blood) xygen had access. Fig. II. represents a portion ken near the end of a capillary blood-clot where, f course, similar conditions would prevail.

The leucocytic reactions and the histological hanges which supervene in tubercle implanted clots re interesting. Polynuclear leucocytes are first ttracted to the tubercle bacilli and phagocytosis llows. The tubercle bacilli now rapidly bring about ne destruction of the ingesting polynuclear leucocytes nd then large and small mononuclear white corpuscles llect and form in concert with the disintegrating olynuclear phagocytes large agglomerations round ne tuberculous foci exactly as described by Borrel in nnexion with the intravenous injection of tubercle acilli. These agglomerates of leucocytes—described y Borrel as miliary tubercles in the making—are own in Figs. III. and IV. A little later—in those gions where the leucocytes do not extinguish the fection—the fibrin meshwork begins to thin out and issolve round the agglomerations of leucocytes which ncompass the clumps of tubercle bacilli (Fig. IV.). he beginning of this process of *cavernation* can be en after 24 hours and after 48 hours definite cavities ave formed, and the process goes on until the slide-ell clots are everywhere perforated with holes. The colorised clots now look like miniature sections of lung riddled with cavities (Fig. IX.). In like manner bercle-implanted capillary blood-clots are gradually oded, and fall to pieces.

Ordinarily two factors—the tubercle bacillus on ne one hand and leucocytes on the other—appear coöperate in the process of cavernation. The bercle bacillus by itself does not—this will be pparent on considering Figs. I. and II.—dissolve p the fibrin. Nor, judging by the case where leucoytes gather round insoluble foreign particles in a lood-clot, do aggregations of unpoisoned leucocytes sintegrate the fibrinous structure. Nor, again, do the ggregations of leucocytes which may collect round aphylococcus colonies dissolve it. Cavernation ould thus appear to be due to a quite special chemical tion exerted upon leucocytes by the tubercle bacillus. n all probability trypsin derived from the disintegrated leucocytes comes into operation on the fibrin. In exceptional cases, where the blood has been very heavily implanted with tubercle, cavitation occurs without any apparent intervention of leucocytes. Here we have cavities filled with badly staining material in which tubercle bacilli are lying loose. Such cavitation is probably produced by a caseating necrosis.

Plasma Culture.

The tubercle bacillus having been found to grow freely in human blood, implantations were made into serum. The event, however, did not conform with expectation. The tubercle bacillus does not proliferate appreciably in serum. Implantations were, as a next step, made into plasma. The technique employed was to obtain blood from the finger to aspirate this into a paraffined pipette, and to centrifuge this without delay in a centrifuge bucket filled with cold water. This done the supernatant plasma was pipetted off, implanted with graduated dilutions of the centrifuged tubercle bacillus suspension, drawn up into capillary tubes, and incubated—control tubes being kept at the temperature of the air. The plasma-clots were then, after one or more days, blown out, were carefully washed to remove the adhering serum, and were then stained with carbol fuchsin and counter-stained. A mere glance at such preparations suffices to show that the tubercle bacillus grows very freely in the plasma-clots (Figs. II. and V.). And when these are compared with blood-clots similarly implanted it is immediately seen that the tubercle bacillus proliferates much more freely and more uniformly in the former than in the latter. Whereas in the case of the blood-clot the colonies are irregularly distributed and come up larger and smaller according as the conditions are in one region favourable and in another unfavourable, in the plasma-clot the colonies are regularly distributed, and are much more of one size. This is obviously what one would expect of microbes implanted into a nutrient medium which was everywhere favourable to their growth.

It would be improper to infer from the fact that the tubercle bacillus proliferates vigorously in a plasma-clot that it is cultivating itself in plasma. In the plasma-clot (and, of course, the same applies to the blood-clot) the microbe is in reality cultivating itself in a medium of serum. The proper conclusion from the facts would apparently be that the tubercle bacillus obtains from the fibrin of the clot some essential nutrient element which is not found in the serum.

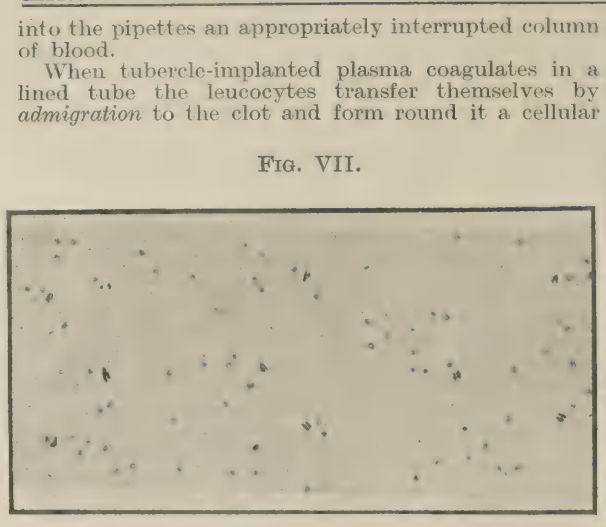
Influence Exerted by Leucocytes Upon the Growth of the Tubercle Bacillus.

We have already seen that the tubercle bacillus grows more copiously and in more uniform distribution in the plasma-clot than in the blood-clot, and we have further seen that in the blood-clot the leucocytes aggregate round the implanted tubercle bacilli, and that the polynuclear leucocytes in particular ingest them. It was, however, desirable to determine by direct experiment whether we can by bringing in the agency of leucocytes check the growth of the tubercle bacillus. This can be put to the test in two different ways. It can be tested by drawing up tubercle-implanted plasma into leucocyte-lined capillary tubes, and comparing the growth in such tubes with that obtained in ordinary unlined capillary tubes. Leucocyte-lined tubes are made by filling blood into ordinary capillary pipettes, incubating, so as to allow the leucocytes to emigrate and fix themselves to the walls, and then drawing a stream of normal salt solution into the distal end of the capillary tube, thereby carrying the clot up into the barrel of the pipette and washing away the red corpuscles and other blood elements. Better for our purpose than tubes furnished with a complete lining of leucocytes are tubes in which only one-half of the stem is lined. And better still are tubes in which leucocyte-lined sections alternate with unlined sections. Such a disposition of leucocytes is obtained by drawing up

into the pipettes an appropriately interrupted column of blood.

When tubercle-implanted plasma coagulates in a lined tube the leucocytes transfer themselves by *admigration* to the clot and form round it a cellular

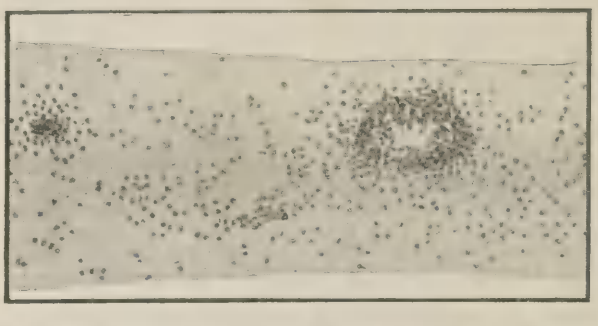
FIG. VII.



Capillary clot from tubercle-implanted normal blood, blown out after three days' incubation, and then hæmolysed by saponin and stained. Practically all the leucocytes have here emigrated from the clot, only a few lymphocytes being left behind. In association with this the tubercle bacilli have grown out unrestrained.

envelope which comes out uninjured when the clot is evacuated through the expanding upper portion of the capillary stem (Fig. VI.). We can accordingly, when we have before us a clot derived from a lined tube, very easily distinguish those regions where the microbes have been subjected to the influence of leucocytes from those where these have not come into operation. Fig. V. shows the growth of tubercle in a section of plasma-clot which has lain in an unlined region of the tube. Fig. VI. shows the growth in an adjoining lined portion. In those regions of a plasma-clot where a sufficient force of leucocytes —and here it is a question of polynuclear leucocytes only—comes into operation the culture of tubercle is,

FIG. VIII.



A similarly implanted and treated blood-clot derived from a patient with phthisis showing leucocytic agglomerations round the tubercle bacilli. In association with this there is a greatly restricted growth of tubercle bacilli.

as shown in the figures, always very much less copious than in those regions of the clot where the leucocytes do not come into play.

Another method of investigating the effect exerted by leucocytes upon the culture of the tubercle bacillus is to fill in tubercle-implanted blood into capillary tubes or flat emigration tubes and centrifuge immediately. We then obtain in the upper half of the tube plasma, and in the lower half of the tube red corpuscles intermixed with polynuclear leucocytes and small lymphocytes; and on the top of this a layer of large mononuclear leucocytes intermixed with the larger lymphocytes. When we now incubate these tubes the tubercle bacilli grow out freely in the plasma-clot; they are, when the implantation is not excessive, killed off in the substance of the red clot, and also, but not so completely, in those regions of the plasma-clot which are invaded by leucocytes. This method may be called the *method of explanting from blood into plasma.*

While it holds true generally that leucocytes exert an inhibitory influence upon the growth of the tubercle bacillus, the rule is subject to important exception. Where leucocytes succumb to tuberculous attack the growth of the tubercle bacillus is distinctly favoured. Examination of implanted blood-clots brings out the fact that polynuclear phagocytosis of tubercle bacilli is generally unsuccessful, and that it then furnishes

FIG. IX.

Photograph of a slide cell tubercle-implanted blood-clot, which was incubated for four or five days and was then hæmolysed by saponin. By "cavernation" the clot has been converted into a sort of honeycomb structure.

new foci of infection, and that the colonies of tubercl that develop from these disintegrated leucocytes ar quite markedly larger than those in other regions o the preparation.

Effect of Implanting Tubercle Bacilli into the Bloods of Phthisical Patients.

When similar implantations of tubercle bacill are made into normal blood and into the blood o patients with pyrexial phthisis—or, to speak mor generally, patients who have reacted to tubercl auto-inoculations—very remarkable differences com to light. There is, in the first place, as will be seen on reference to Figs. VII. and VIII., a difference with respect to the leucocytic reaction. Whereas th leucocytes of normal blood when the blood is heavily implanted collect only sparingly round the tubercl bacillus, most of them emigrating from the clot, th leucocytes of the tuberculous patient congregate in great masses round the bacilli. In correlation with this greater leucocytic reaction a more powerfu destructive effect is exerted upon the implanted bacilli, and when we compare tuberculous and norma blood, counting in each case the number of tuberculou colonies in the incubated and unincubated blood w find there is in the blood of the tuberculous patien a much larger dissolution of microbes.

There is here much food for thought. It is in th first place obvious that though there are clinica similarities between pyrexial phthisis and chroni streptococcal septicæmia the immunological condition

are in the two profoundly different. In the septicæmic patient the hæmo-bactericidal power is as compared with the normal, very conspicuously reduced. The treatment of streptococcal septicæmia should by consequence be *epiphylactic*. In other words, it must aim at increasing the bactericidal power of the blood. The pyrexial tuberculous patient here in view has, as compared with the normal, a greatly increased hæmo-bactericidal power. *Epiphylaxis* is therefore here not the essential requirement. And we have to ask ourselves what can here be at fault and what treatment is required? The answer to these questions would seem to be that the infecting tubercle bacilli are cultivating themselves in *ecphylactic* foci, and that *kataphylactic* treatment is called for. In other words, the bactericidal agents, that is the leucocytes, should here be transported from the blood into the regions of infection. That is precisely what we do when we introduce a tubercle-implanted plasma-clot into a lined capillary tube (Figs. V. and VI.).

The essential preliminary to treatment on these lines will obviously be the prosecution of research into the phenomena of emigration. We require to study the laws that govern the emigration of the leucocytes from the blood, or, as the case may be, blood-clot. We require to find out how to make leucocytes invade the tubercle foci as they *admigrate* to the bacilli in the bloods of tuberculous patients. And we require to study generally the chemotactic properties and the migrational movements of the different species of leucocytes.

Comparison of Normal Blood Inoculated in Vitro with Koch's Bacillary Emulsion with Uninoculated Normal Blood.

As an inducement to other workers to take up the study of this question, it may be placed upon record here that the increased leucocytic reaction and the increased tuberculo-bactericidal power which distinguish the blood of tuberculous patients who have reacted to auto-inoculations can be obtained by the addition of bacillary emulsion to the normal blood in vitro. But in connexion with this it must be borne in mind that here, as in all immunisation, the immunising result will depend upon two factors operating in conjunction. The first is the dose of living microbes implanted. The second is the quantum of vaccine which is superadded. The following results apply to blood implanted fairly sparingly with living tubercle bacilli. With small additions of bacillary emulsion—i.e., doses ranging above and below 1 in 50,000,000 of bacillary emulsion in blood—very large reduction of the tuberculous growth is obtained. With larger doses—doses up to 1 in 5,000,000 of bacillary emulsion in blood—increased agglomeration of leucocytes round the tubercle bacilli is obtained. But with these larger doses the tubercle bacilli dispersed in the other regions of the preparation appear to grow more plentifully.

In conclusion, I desire to thank my friend and colleague Alexander Fleming, F.R.C.S., for the drawings which illustrate this paper.

A NEW METHOD OF PREPARING VACCINES.

BY DR. RÉNÉ ZIVY (PARIS).

SINCE the first vaccine was prepared by devitalising bacteria at 120° C. (antityphoid vaccine of Chantemesse and Widal, 1888) up to the introduction of the present method of successive heatings to 56°–57° C., bacteriologists have constantly been endeavouring by various means to reduce as much as possible the degree of heat necessary for sterilisation, it being known that devitalisation at a high temperature diminishes vaccinating properties and increases toxicity. I considered it probable that alteration of the albuminoid substances by a high temperature was the cause of the incomplete results and the general or local consecutive troubles usually observed. Chemical products, such as iodine, ether, phenol, used also for sterilising vaccines, seem to me to have the same inconveniences.

I have therefore considered killing bacteria by means of freezing. All previous researches on the action of continuous cold on bacteria (Pictet and Yung, d'Arsonval and Charrin) demonstrated that bacteria became accustomed to this new condition of existence, lived, and were reproduced at the lowest temperatures. The question was, therefore, to prevent such a continuation of existence, and for that purpose I submitted bacteria to successive freezings and thawings. On searching the work already published on this matter, I found in the *New York Medical Record* of 1887 an article by Mr. Prudden, reporting experiments made with a view to the sterilisation of drinking water, and his conclusions were completely in accordance with the results of my own experiments.

I succeeded in obtaining complete sterilisation by a very simple process: The cultures on gelose are emulsified in physiological salt solution. This solution is dosed with the opacimeter, 50 milliards per c.cm. The solution contained in an aluminium tube (glass tubes cannot be used, as they break and were the cause of failure in my first experiments) is placed in a freezing apparatus with a constant temperature of −18° C. This temperature of −18° C. is obtained in the interior of the aluminium tube in about one hour and a half. The tubes are left in the freezing apparatus for five hours, taken out and left another five hours at room temperature (about 16° C.). Thus freezing and thawing has taken place.

According to the species of bacteria this operation must be repeated twice for pneumococci and streptococci, four times for *B. coli*, and six times for staphylococci and enterococci. On completion of the requisite number of periods in the freezing apparatus, sterilisation is complete (as we have proved by sterility of cultures tested during the last three months). The original solution is then diluted with physiological salt solution in order to obtain the required dosage.

In the course of my experiments I found it useless to put the cultivated gelose itself into the freezing apparatus. After 20 periods of freezing the microbes were still living. In order to study the toxicity of these vaccines, I have used a mixed vaccine containing in each cubic centimetre: pneumococci, streptococci, enterococci, staphylococci, *B. coli*, each 100 mill., altogether 500 mill. bacteria; 1·5 c.cm. of this vaccine (750 mill. bacteria) were injected into the vein of a rabbit weighing 2·800 kg. and caused no trouble, not even trembling. The non-toxic dose is, therefore, over 300 mill. bacteria per kg. weight of animal. The dose I have generally employed in man is only 500 mill. bacteria.

FOOT-AND-MOUTH DISEASE IN RATS.

BY J. M. BEATTIE, M.A. N.Z., M.D. EDIN.,
PROFESSOR OF BACTERIOLOGY, UNIVERSITY OF LIVERPOOL;
AND
DAVID PEDEN.
(*From the Bacteriological Department, University of Liverpool.*)

ABOUT the middle of December last a number of glands, mainly pre-scapular, from cows were brought to the laboratory for examination. They had been collected by the chief city meat inspector, who considered them abnormal, and following his routine practice he sent them for examination and report. The glands were enlarged, some of them inflamed, the pulp being soft and œdematous, while others showed irregular and more or less extensive hæmorrhages. Scrapings from the glands were made, but no special changes, other than those observed with the naked eye, were present. Neither bacteria nor protozoa were found. Cultures gave growths of a short-chained

streptococcus which, at first, was best developed under anaerobic conditions; later, this organism grew quite actively as an aerobe. We did not attach much importance to this organism as no special precautions had been taken in collecting the glands. A further series of glands, received at a later date, showed exactly the same conditions.

All the glands had been taken from carcasses of cows slaughtered because they had been in contact with cases of foot-and-mouth disease. None of the animals showed any of the usual signs of this disease, and they had been sent to the abattoir as non-infected. The fact that these cows were from an infected farm or dairy added special interest to the examination, and we carried out a series of experiments which have led us to believe that some of these glands contained the virus of foot-and-mouth disease, and that the disease could be produced in some laboratory animals. The work is still incomplete, but the results so far obtained and confirmed, are, we think, of sufficient importance to justify publication.

Description of Experiment.

On Dec. 18th, 1923, a rat (*a*), a mouse (*a*), and a rabbit received a subcutaneous inoculation of a saline emulsion of the glands, and a mouse (*b*), a rat (*b*), and a guinea-pig were fed on the minced glands. They received one feed only, but the guinea-pig was also given a subcutaneous inoculation.

On Jan. 1st, 1924, the guinea-pig died. There was no evidence of any lesions in the feet or in the mouth, but all the glands in the regions of the jaws were enlarged and contained a semi-solid yellowish purulent material. There was marked injection of the intestines, and some serous fluid in the peritoneal cavity. This fluid was crowded with inflammatory cells, mainly of the mononucleated type. Cultures from this fluid and from the glands yielded a short-chained streptococcus, and a small Gram-negative coccus. Both these organisms were pathogenic to rats and guinea-pigs; the Gram-negative coccus produced very marked gelatinous œdema at the site of inoculation, but we have no evidence, at present, to show that these organisms had any causal connexion with the disease. The rabbit showed no sign of infection and is still alive; mouse (*a*) died of streptococcal septicæmia.

On the 4th, rat (*a*), which had received the subcutaneous inoculation, died. There was well-marked œdematous swelling on the dorsum of both hind feet. The tail had been completely bitten off at the root. No special lesion was noted in the mouth, and, unfortunately, the lungs, which in the later animals showed important lesions, were not examined. A rat (*c*) was vaccinated on the dorsum of one of the left hind feet with the clear serum from the swollen foot of rat (*a*); only a very minute drop of the serum was used.

On the 10th, rat (*b*), which had been fed on the cow glands, was killed. It had shown for one week marked œdema of the dorsum of both its hind feet (the right foot was held off the ground on the day on which the animal was killed). The œdematous condition was exactly similar to that observed in rat (*a*), but, in addition, there was a very distinct small vesicle with clear fluid in the dorsum of the tongue, and on the anterior under surface a definite small ulcer. The tail was very much swollen, and about half of it had been bitten off. Both lungs showed infarct-like areas of gelatinous œdema with, here and there, distinct vesicle formation on the pleural surface.

On the 12th, a rat (*i*) was fed on a second series of cow glands, and a rat (*j*) was inoculated with an emulsion from the same series of glands.

On the 16th, rat (*c*), vaccinated on the 4th, was killed. This rat had been ill for several days after the vaccination, and there was definite swelling of the vaccinated foot. This evidently was due to the irritation, and subsided in a few days; but the swelling returned and the dorsum of the opposite foot became swollen. The rat in its general condition was much improved, and would probably have made a complete recovery. On examination, besides the œdema noted, two small scars, very suggestive of ruptured and dried-up vesicles, were seen one on the under surface and the other between the toes of the right hind foot. There were two small unruptured vesicles on the dorsum of the tongue near the root, and in the lungs there were numerous irregular areas of gelatinous œdema.

On the 17th, rat (*i*), fed on Jan. 12th, was examined under an anæsthetic. The feet were red and inflamed, and there were three distinct vesicles, two of them hæmorrhagic, on the under surface of the toes of the left foot. Rat (*j*) showed distinct œdematous swelling of the dorsum of both feet.

On the 19th, mouse (*b*), fed on Dec. 18th, died. The mouse had been ill, but appeared to have recovered completely, with the exception of the tail which remained considerably thickened. On examination no lesions were found in the feet or tongue, but two gelatinous œdematous areas, similar to those seen in the rats, were present in the lungs.

On the 21st, rat (*i*), fed on the 12th, was killed. There was very marked œdema of both hind feet, especially the right foot. This was more marked than in any of the previous animals. There were definite vesicles on the under surface of both hind feet and between the toes. The tongue showed two minute vesicles, one on the lateral aspect and one on the dorsum near the root. Both lungs showed a very large number of the areas of gelatinous œdema noted in the other rats. Rat (*j*), inoculated on the 12th, was also killed; it showed besides the œdematous swelling of the feet, several very well-marked vesicles on the under surface of both the hind and fore feet. There was no lesion in the mouth, but the œdematous patches were present in the lungs.

Summary.—Four rats which have been fed on, or inoculated with, cow glands have developed œdematous swelling of both hind feet, two have shown, in addition, clear vesicles on the under surface of the feet or between the toes, two have vesicles on the tongue, three, and one mouse, had vesicles or patches of gelatinous œdema in the lungs (the lungs of the fourth were not examined). One rat was vaccinated with a very small drop of the œdematous fluid from the foot of an infected rat, and this animal also developed the œdema of the feet, the vesicles on the under surface of the toes, vesicles in the tongue, and the gelatinous œdema in the lungs.

Discussion.

Since making these observations we have examined 80 healthy rats, and no trace of similar lesions in the feet, mouth, or lungs were found, and in a very large experience with rats no similar condition has been seen by us. The special localisation of the lesions in the feet and the tongue are similar to those found in foot-and-mouth disease; the special and unique condition in the lung has, so far as we know, never been described. The results were obtained with specially inflamed glands from cows which had been contacts with foot-and-mouth disease. With such glands no rat has failed to produce the condition.

If the condition we have produced in these rats is foot-and-mouth disease, and we see no reason to doubt this, and if the experiments are confirmed, a very important avenue for investigation has been opened up, for the following reasons:—

1. The carriage of the disease from place to place either by the infected rat itself (and we know that rats migrate over considerable distances), or by the foodstuffs in which the rats live and die, is, at any rate partially, if not wholly, explained.

2. The vesicular condition on which diagnosis at present depends may merely be a manifestation of some deeper infection—just as herpes may be an outward sequel of a pneumonia, and that the distribution for food of the flesh of contact animals may be a source of spread of the disease.

3. If the disease can regularly be produced in rats the great difficulty of experimental investigation and the supposed risks are considerably reduced. Rats can be very easily isolated, and work in relation to the cultivation of the virus can be carried out with very little difficulty, and, in our opinion, without the slightest danger.

Our great regret is that we have not been able to experiment with material from animals known to be suffering from the disease. We have asked for it but have been told that the risk is too great, and we therefore publish these experiments in the hope that we, or others, who are working at the subject may be given reasonable facilities to carry out a thorough investigation into a disease which has cost so much to the nation.

NOTE.—Another rat which received one feed of blood from rat (*b*) on Jan. 10th now (Jan. 22nd) shows very typical swelling of the dorsum of both hind feet, two small vesicles on the tongue, and one very typical vesicle full of gelatinous fluid on the pleural surface of the right lung.

STEINACH'S REJUVENATION OPERATION.

BY KENNETH M. WALKER, F.R.C.S. ENG.,
HUNTERIAN PROFESSOR; SURGEON IN CHARGE OF GENITO-URINARY DEPARTMENT, ROYAL NORTHERN HOSPITAL AND MILLER HOSPITAL FOR SOUTH-EAST LONDON;

AND

J. A. LUMSDEN COOK, M.B., CH.B. EDIN.
ASSISTANT MEDICAL OFFICER, ST. MARY ABBOTS HOSPITAL, KENSINGTON.

OF recent years great interest has centred round the operation of ligature of the vas as a method of stimulating the output of the internal secretion of the testis. This has been due in great part to the experimental work carried out by Prof. Steinach, of Vienna, on the results of ligature of the vas in senile animals. Other workers before Steinach, and notably Ancel, Bouin, and Kuntz, had described the effect of vasoligature in the case of young animals, and had shown that the operation produced a state of heightened sexual vigour, but Steinach was the first to apply the method to senile animals in the hope of stimulating their failing energies. His work was done on the rat, an animal particularly well suited for experiments of this kind, owing to the fact that its life is a short one and that symptoms of age are easily recognisable. The results of his experiments were published in 1920 in a monograph entitled "Rejuvenation by Experimental Revivification of the Senile Puberal Gland."[1] The title was perhaps an unfortunate one in that it encouraged the raising of extravagant hopes and resulted in the premature exploitation of a method of "rejuvenation" that had not been sufficiently tested. However, the fact that Steinach's work was soon exploited by some of the less reputable members of the medical profession does not detract from its value and interest. Indeed, the mere fact that because of its exploitation it has received but little attention in this country is sufficient justification for such an article as the following, and for this reason no apology need be offered for dealing with the matter in greater detail.

Steinach's Animal Experiments.

In his animal experiments Steinach used white rats and crossings between these and the wild rat. The average life of these animals is 28 months, and signs of old age usually appear about the twentieth month. The indications of old age most easily recognisable in the rat are loss of weight, appetite, and energy, depressed carriage of the head, lack of interest in its surroundings, loss of pugnacity, diminution or complete disappearance of sexual vigour, and deterioration of the coat, with loss of hair, uncleanliness, and increase of parasites. These outward signs are accompanied by less obvious changes in the genitalia and particularly in the secondary sex glands, such as the prostate and vesicles. The latter instead of forming large and convoluted sacs distended with fluid, as in the young animal, appear wrinkled and shrunken in size, containing only a minimum of seminal secretion.

Previous to operations Steinach's animals were subjected to a series of tests, in order that precise data might be available for estimating any improvement occurring subsequent to the ligature. Tests of muscular energy were carried out by placing the animals' food in such a position that it could only reach it by climbing or leaping. As a test of courage young pugnacious males were introduced into the same cage and the disposition and ability to defend itself shown by the old animal was carefully noted. Sexual vigour was estimated by placing the rat in proximity to females both on heat and in the resting state. A record was also kept of the amount of food consumed in 24 hours, the weight of the animal, the condition of its coat, its ability to keep itself clean and free from parasites, the interest it displayed in new surroundings, and its general behaviour when alone in its cage.

When an accurate estimate of the condition of the animal had been reached, bilateral section of the vas between ligatures was carried out. In one or two cases, in order that a record might be kept of the condition of the internal organs, and especially of the prostate and vesicles, a laparotomy was performed at the time of ligature and subsequently when signs of rejuvenation had manifested themselves. As a rule no alteration of the condition of the rat was noted for a period of two to four weeks after operation. The first sign of change that manifested itself was a return of sexual excitement when in the presence of a female rat. With the increase in sex vigour came a renewal of pugnacity, an alteration in the carriage of the head, an increase in appetite and in muscular energy, and an improvement in the coat with a new growth of hair, especially on the scrotum and around the external genitalia. In some of the cases recorded by Steinach the return of sexual vigour was so marked in these senile animals that for a time they equalled in potency the young males. At the end of a period that was anything from five to seven months after ligature the condition of the rejuvenated animals showed signs of deterioration. Potency became less strong, muscular energy and courage declined, the appetite diminished, and signs of senility returned. These gradually became more intense, so that finally the animal sank into a condition of apathy and died, usually within a few weeks of the onset of the relapse. Not infrequently the terminal cause of death was shown post mortem to have been some pulmonary condition.

In addition to studying the general results of vasoligature on his animals, Steinach carried out a careful histological study of the associated changes that occurred in the testicle. He found, as had Ancel and Bouin before him, that ligature brought about a degeneration of the seminal epithelium, and an increase in the interstitial tissue. More difficult to explain is Steinach's observations that when only one of the two testicles were tied an increase of interstitial tissue was found on the untouched side as well as on the side of the ligature, although, of course, in the former case there were no signs of degeneration in the tubules. It is of interest to note that the changes in the testicle, whatever their nature, occurred not immediately after the ligature, but after a latent period of two to three weeks. (See Fig. 1.) Of still greater interest is the fact that the degeneration observed in the tubules was not permanent, but that after an interval of six to eight months had elapsed since the application of the ligature, the majority of tubules were found to have completely regenerated. This phenomenon of regeneration has also been noted by other investigators, especially by Kuntz, who found that if a dog whose vas had been ligatured were allowed to survive 142 days, and the testis then examined, the seminal epithelium was normal in appearance and active spermatogenesis was present. The fact that in these cases the vas was still dilated on the side of the ligature showed that the duct was still occluded and that the regeneration was not merely the result of a renewal of patency. Sands states that although after ligature of the vas he found an increase in Leydig cells, associated with degeneration of the tubules, he was not able to demonstrate to a certainty this regenerative phenomena. However, additional weight is given to the evidence in favour of Steinach's and Kuntz's observations by the fact that epithelial regeneration has been observed in other glands after ligature, and notably in the pancreas. Bensley has clearly proved by means of his intravitam methods of staining that although islets and acinar tissue degenerate after ligature of the pancreatic duct, both tissues subsequently become regenerated.

[1] Verjüngung durch experimentelle Neubelebung der alternden Pubertätsdrüse.

Criticism of Steinach's Animal Experiments.

A criticism of Steinach's experimental work divides itself naturally into two parts: first, a consideration of the effects produced in the general condition of the animal by ligature, and second, the relation of these phenomena to the histological changes observed in the testicle. Whatever may be the verdict that science will eventually pronounce on the effect of vaso-ligature when carried out in the human being, and however sceptical we may remain of the so-called rejuvenation obtained by exponents of this operation, it is certainly difficult to offer any explanation of the

FIG. 1.

Section through the testis of a rat five weeks after ligature and division of the vas. The section shows a marked degree of degeneration in the tubules, together with an increase in prominence of the interstitial tissue.

remarkable results obtained by Steinach in his animal experiments other than the explanation which he himself furnishes—namely, that ligature of the vas, by increasing the output of internal secretion, thereby stimulates the endocrine system generally and reawakens the waning energies of the senile animal. Whether, in addition to bringing about a condition of renewed activity, the operation of vaso-ligature has any effect in actually prolonging the duration of life is an entirely separate question, for as Steinach himself has pointed out, the span of life of a single individual can never be predetermined, so that definite proof of prolongation must inevitably be lacking. It is noteworthy, however, that several of the animals ligatured by Steinach reached an unusually advanced age, one of them living three years, and thereby surviving a brother born in the same litter and dying of normal decay by seven months. If we accept the account given by Steinach of his experimental work we are almost bound to accept his theory, for no other explanation of his results is available. Fiebinger's suggestion that the rats used in these experiments were not suffering from old age but from mange, and that the improvement in their coats and general condition was the result not of the ligature but of the good feeding and attention they received in Steinach's laboratory, is scarcely sufficient to explain his results when we keep in mind the completeness and ingenuity of the tests to which the animals were subjected before ar after operation.

Surprising as are claims made by Steinach, ar difficult as it may be to account for all that he describe it is impossible to do otherwise than to acce Steinach's work with an open mind and await co firmation of his results by other observers of equ scientific standing. By the courtesy of Prof. Steina we are enabled to publish photographs of two ra showing the effect of ligature. The descriptions a taken from his work "Verjüngung." (See Figs. and 3.)

If we turn now to a consideration of the second pa of Steinach's work—namely, the relationship of t phenomena of rejuvenation to the histological chang observed in the testis—we find ourselves confront with a far more complex problem. Like Ancel ar Bouin, Steinach found that ligature was follow by degeneration in the seminiferous tubules ar increase in the interstitial cells. Accepting An and Bouin's view that the latter cells are the so source of the internal secretion of the testis, naturally claimed that the histological changes fou in the testis furnished additional proof that by l ligature he had stimulated the output of sex hormo Granted the truth of Ancel and Bouin's theo Steinach's line of argument was logical. If, howev we do *not* accept the dictum that the interstiti cells are the sole source of the internal secretion of t testis, we cannot accept an increase in the interstit tissue as a proof that the output of sex hormone h been stimulated. In a previous article published THE LANCET of Jan. 5th, one of us (K. M. W.) furnish arguments for believing that the interstitial cells w not the sole source of formation of the inter secretion of the testis, and for this reason we are n inclined to accept in its entirety the interpretati that Steinach places on his histological observatio The increase in interstitial material observed af ligature would, in our opinion, indicate not an increas output of hormone but an accumulation of nutri material resulting from a diminished activity of t tubules. If this view is correct the significance Steinach's histological findings would be lost, but t value of his observations with regard to the effect vaso-ligature on the general condition of the sen animal remains unimpaired.

Ligature of the Vas in the Human Subject.

Since the publication of Steinach's work vas ligature has been tried in man with variable resul Before considering the subject it will be advisable deal with an objection that has been raised agai the possibility of ligature of the vas exercising a rejuvenating effect on man. It has been urged th at one time the operation of ligature of the vas w carried out fairly extensively as a treatment f enlargement of the prostate, and that no rejuvenati results were reported to have resulted from the p ceeding. This objection is not so weighty as would at first sight appear when one remembers t method of applying the ligature in these cases. T treatment of prostatic enlargement by means ligature of the vas was introduced by Mears in 18 but in ligaturing the vas so little care was exercised avoid damaging the blood- and nerve-supply of t testicle that a large number of cases of gangre followed. It was, indeed, partly because of the accidents that the method was afterwards abandon As avoidance of interference with the blood-supply the testis is a sine qua non of the procedure advocat by Steinach, the crude method of ligature employ by Mears and his followers cannot be regard as an instance of the application of vaso-ligatu to man.

During the last six years numerous workers ha employed Steinach's methods in the human subje amongst others Lichtenstern, Peter Schmidt, Lev Lenz, Benjamin, and Knud Sand. Owing to the fa that ligature of the vas sometimes causes the form tion of a spermatocele, and that this is likely

embarrass the blood-stream of the testis, Sand and Tournade have abandoned the operation of ligature of the vas in favour of a partial epididymectomy. Sand's technique consists in carefully freeing several centimetres of the upper part of the epididymis from the body of the testis, taking care to avoid injuring the fine vessels and nerves proceeding to the latter structure. After isolation has been completed the freed portion of the epididymis is resected between ligatures. The whole operation is conducted under local anæsthesia through a small incision in the upper part of the scrotum. Other workers content themselves with tying the vas, the ligature being placed low down near its junction with the epididymis. Equal care must be exercised to avoid damaging the blood-vessels.

Results.

Nothing is more difficult than to assess the clinical results of ligature of the vas in man. This is due not only to the absence of definite measurable data by means of which improvement can be gauged, but also to the fact that it is almost impossible in the human subject to exclude the action of mental suggestion. Moreover, difficulty is generally experienced in selecting cases suitable for operation, since pure senility unassociated with such complications as bronchitis, cardiac lesions, &c., is of uncommon occurrence, and variations and improvements in the secondary lesions are likely to obscure and confuse the issue. All that it is possible to do in the present paper is to append reports of cases treated by the writers by means of vaso-ligature, and to supplement this with an account of the results obtained by other workers. It must be realised, however, that in practically all the cases of vaso-ligature recorded by exponents of the operation of vaso-ligature the proof that improvement resulted rests on evidence of a more or less doubtful nature. On this account a very large number of observations will be necessary before it is possible to pass judgment on vaso-ligature as a method of treatment.

Of 18 cases reported by Sand, 13 were cases of senility and five cases of impotence associated with neurasthenia. Out of the 13 cases of senility the author reports nine favourable results, the criteria by means of which success was gauged being increase in the weight of the patient, renewal of mental and physical vigour, a return of virility, and a subjective or objective appearance of well-being. In two additional cases any favourable results that may have followed the operation were only temporary in character, and in two the results were entirely negative. Of the five cases treated for conditions other than senility two only resulted favourably. Benjamin reports 16 cases treated by ligature, with nine positive results, four doubtful, and three negative. Lichtenstern states that he has performed the operation in 60 patients and claims satisfactory results, although we have been unable to obtain details of his patients or to discover precisely the criteria by means of which he gauges his results. In some of Lichtenstern's cases ligature would appear to have been carried out without the patient's knowledge during the course of another operation, so that the effect of suggestion could to a great extent be excluded.

Levy-Lenz and Schmidt report cases of failure and also of success. In the opinion of the latter no good results may be expected when the testicle of the patient shows marked senile atrophy. This, of course, is only to be expected when it is remembered that the whole success of the operation is dependent on the power of the testis to respond by increased output of hormone to the stimulus of ligature. All observers remark on the variable latent period that occurs in positive cases before any improvement is noted. Sands states that in some of his cases the beneficial effect of ligature was delayed for as long as six months. Various explanations may be offered for this long latent period. Amongst others the fact that regression in the tubules does not immediately follow the application of the ligature.

FIG. 2. FIG. 3.

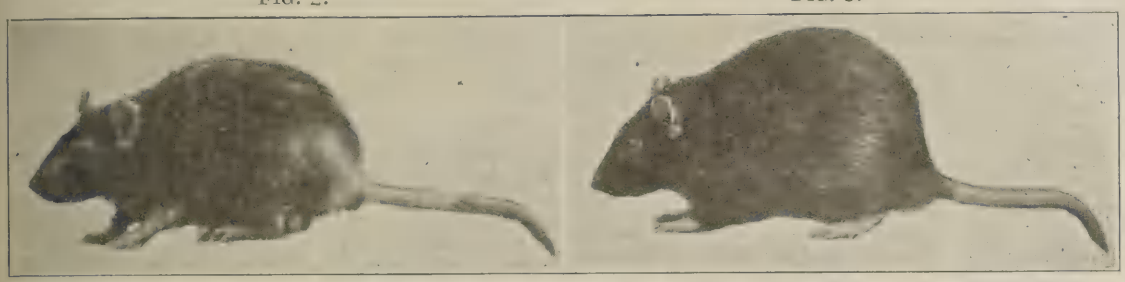


FIG. 2 shows a rat with marked signs of senility (26 months old). The emaciation, thinness of the fur, and sleepiness (eyes closed) of the animal are striking. The back, hips, upper part of the thigh, and portions of the feet are quite bald.
FIG. 3 shows a brother of the same litter, three and a half months after vaso-ligature. According to Steinach, this animal at the time of operation presented an even worse appearance than its brother (Fig. 2), so that on account of its apparently hopeless condition it was not even photographed or registered. "In spite of this complete regeneration and revival of functions took place, although after a longer latent period and more slowly than in the case of other senile animals. The animal survived the operation about ten months and its brother by eight. Three months after ligature it was a fine, strong animal with a coat completely restored, eyes that sparkled, and a youthful mien." (Photographs and descriptions kindly supplied by Prof. Steinach.)

Table showing Changes following Vaso-Ligature in Three Human Patients.

Case.	Age.	Died of—	Period elapsed since ligature.	Findings in (*a*) control testis; (*b*) ligatured testis.
1	78	Epithelioma of tongue. Cachexia.	Days. 17	Leydig cells: (*a*) Fair number; (*b*) increased. Tubules: (*a*) No spermatogenesis; (*b*) no change.
2	63	Sarcoma of jaw. Cachexia.	52	Leydig cells: (*a*) Fairly numerous; (*b*) no obvious increase in number. Tubules: (*a*) No spermatogenesis; some tubules show marked degeneration; (*b*) still greater signs of degeneration present.
3	71	Uræmia.	78	Leydig cells: (*a*) scanty; (*b*) increased in number. Tubules: (*a*) Spermatogenesis; (*b*) spermatogenesis still present; early signs of degeneration in a few tubules.

Note.—In Cases 1 and 2 there were no signs of reaction in the tubules as the result of the ligatures, and in Case 3 only very early indications of degeneration were visible. In two out of the three cases an increase of interstitial tissue had taken place.

Although numerous observations have been recorded of changes occurring in the testes of animals after ligature, no records are available of the histological changes occurring in the human subject. For this reason we took the opportunity of carrying out ligature of the vas in three cases suffering from

malignant disease and renal failure, and of examining post mortem the changes that had followed the placing of the ligature. Although the fact that the patients were suffering from severe cachexia somewhat prejudices these observations, the results obtained are sufficient to show that the time taken for marked changes to appear in the tubules of the human testis after ligature is considerable, probably two months or more.

Treatment of Paralysis Agitans by Vaso-Ligature.

Of the four patients treated by means of vaso-ligature, whose histories are given below, three were cases of paralysis agitans. The failure of every known form of treatment to alleviate this condition justified, in the writers' opinion, a trial of vasotomy. Dubief, in discussing this disease, states that "paralysis agitans has for an anatomical basis the lesions of cerebral spinal senility which differ only from those of true senility in their early onset and greater intensity." The employment of Steinach's operation, therefore, seemed particularly appropriate. Although some improvement was noted in two out of the three cases this improvement was much the most striking in the first case reported. It is true that allowances must be made in this instance for the nursing, care, and food the patient received on admission to the hospital, and that some of the improvement may be put down to these factors. However, the alteration in the patient's condition after each of the ligature operations was so marked that it is difficult to believe that it bore no relation to these proceedings. The fourth case reported was a patient in good health, who requested that bilateral ligature of the vas should be carried out for purposes of sterilisation.

CASE 1.—Patient, aged 63, admitted to St. Mary Abbots Hospital Oct. 7th, 1923, suffering from paralysis agitans.

History.—Tremors and increasing rigidity for a period of three years prior to admission. Complete loss of control of anal sphincter for two years.

Condition on Admission.—Typical mask-like expression, with general muscular rigidity and marked clonic movements of the head, trunk, and limbs (pill-rolling). Articulates only with difficulty. Patient very emaciated, completely bed-ridden, and unable even to turn in bed without assistance. A very marked stoop; when propped in a chair his body falls forward so that he has to be placed again in an upright position. Complete incontinence of fæces, the patient being conscious of desire to evacuate the bowel, but unable to wait until the bed-pan arrives. Unable to feed himself, spills fluids when trying to use a cup, and fails entirely to guide food into his mouth. Grip on both sides very poor, movements are continuous throughout the day, and the patient rests badly at night, owing to jumping in his sleep. Sexual desire decreasing for some years and completely absent for 12 months before admission.

First Operation.—On April 4th division of the right vas between ligatures. About four weeks after operation the patient began to show signs of improvement, the first manifestation being an improvement in articulation. Muscular rigidity and tremors diminished so that he was able to balance himself on his feet and to walk, but with some difficulty. However, he still found it impossible to turn round without support. Control of the sphincters was also regained, and the weight and appetite increased. The improvement continued so that he became able to feed himself with slight difficulty. The tendency to fall forward when sitting in a chair diminished, and the clonic movements disappeared entirely with the exception of those of the hands; even these were reduced in severity. Associated with the improvement in the physical condition was a more cheerful mental state and greater tranquillity at night.

Second Operation.—Owing to the patient's improvement as the result of the previous operation, there was no difficulty in obtaining his permission to carry out a similar proceeding on the opposite side. This was accordingly carried out on August 31st. Four weeks after the second operation sexual desire returned, accompanied by daily erection. The patient now stands almost straight, walks up and down stairs with ease, turns round unaided, and moves in bed without assistance. He feeds himself without difficulty, and his appetite has increased still further. There is a marked diminution in the mask-like expression, a change that has been commented on by several relations. He sleeps very well, retains complete control of his sphincter, and the movements have disappeared except for some pill rolling that returns when the patient is excited. There is still some rigidity of the muscles. The grip is good for a man of hi age. On Jan. 12th it was noted: "sexual desire still main tained. General condition still remains good; there i little new to add since the last note."

CASE 2.—Patient, aged 55, admitted to hospital o July 24th, 1923, suffering from paralysis agitans.

Condition on Admission.—Weakness of right arm and leg the grip being poor on that side, and the leg dragged whe walking. Right leg slightly flexed. Rigidity and marke clonic movements of right hand and arm continuous through out day. Owing to weakness on right side is unable to hol a cup. Typical mask-like expression.

Operation.—Unilateral vasotomy was performed on th 27th.

Subsequent History.—On Jan. 12th, 1924, there is diminution in the tremors of the right arm, which are no only marked during excitement. No improvement in th condition of the right leg, or in the grip; no alteration i mask-like expression. The patient's general conditio would appear to have improved, and the tremors to hav diminished, but the effect has been much less than tha observed in Case 1.

CASE 3.—Patient, aged 50: in 1917, when in command a battalion in France, noted twitchings of the right hand which gradually increased in intensity and afterward affected the right foot, so that in walking he failed to cle the ground with his heel. In 1918 a diagnosis of paralys agitans was made. In spite of his illness he remained hard at work on home service, and in 1920 began to suffe considerably from nocturnal emissions, which left him t following day with an intense headache and a feeling depression. It was for these emissions in particular tha he consulted me, and at Dr. C. B. Heald's suggestion I agree to try the effect of vasotomy.

First Operation.—Ligature of right vas, Dec. 19th, 192 Subsequent to the operation emissions diminished very muc in frequency as also did the headaches.

Second Operation.—Ligature of left vas, May 19th, 192 Following this operation the emissions practically di appeared, and the patient no longer suffered from headache He still remained at work, but under great difficulties, an with a steady progression of the signs of muscular weakne and tremor. Although the operation had cured the conditi for which the patient sought relief, it appeared to have ha little or no influence on the general progress of his disease.

CASE 4.—Patient, aged 63, in good health, but operat on at his own request with a view to sterilisation.

Operation. Bilateral division of the vas betwee ligatures, June 6th, 1923.

Subsequent History.—In order to avoid the effect mental suggestion, little was said concerning the possibili of the operation having a beneficial effect on the gener health. The patient was requested to write and furnish a unbiased statement of his general health some 5 mont afterwards. The following is the letter received: "I a glad to tell you that I am quite well in health, and fe younger and more sprightly than for years. I am not s nervous, my sight has improved, and my sciatica has gon Whether all these benefits are due to the operation I cann say for certain, but I think so."

Conclusions.

At the present time there is insufficient materi on which to base a decision as to the value of vas ligature as a means of treatment in man. The result of the operation appear to have been capricio although numerous cases are reported in whi benefits accrued. As, however, the data on whi the claims of improvement rest are inexact an incapable of measurement, a large number of observa tions will be necessary before it will be possible bring in a final verdict as to the precise value of th form of treatment. However, whatever the verdi concerning this clinical problem may be the resul obtained by Steinach in his animal experiment a certainly of the greatest biological interest.

A CONSIDERATION OF THE AFTER-RESULTS OF THE ABDOMINAL OPERATION FOR RETROVERSION.

WITH NOTES OF FIFTY CASES.

BY ALICE BLOOMFIELD, M.D. EDIN., F.R.C.S. ENG.,

LATE RESIDENT MEDICAL OFFICER, HOSPITAL FOR WOMEN, SOHO-SQUARE, W.

MUCH discussion has recently arisen as to the clinical significance and necessity for operative treatment in cases of retroversion, and it has appeared to me that a useful purpose might be served by recording a series of cases showing the results of 50 abdominal operations for this condition. Retroversion is a condition of great frequency, Schroeder[1] finding it in 25 per cent. of medical cases, with no pelvic symptoms, while L. J. Stacey[2] found the uterus retroverted in 202 out of 11,000 single women examined, between the ages of 15 and 45. Its clinical significance, and therefore the necessity for and method of treatment, is, however, very variously estimated.

Previous Views of the Subject.

Looking through the literature on the subject, I have been struck by the fact that practically all writers include cases of prolapse when recording the after-results of their operations for retroversion. This seems to me to introduce an element of doubt into statistics, and to falsify the latter. In considering both the symptomatology and treatment of retroversion a definite distinction should, I think, be made between cases of retroversion associated with descensus of the pelvic viscera and weakness of the pelvic floor and cases in which no such condition is present. Possibly it is the inclusion of the former, when considering the symptomatology, &c., of retroversion that has led to such divergent opinions being held about the condition. These cases should, I think, always be included under the heading "prolapsus," as they are simply part of the mechanism in the production of this condition, and differ from the second group of cases mentioned above in that they usually give rise to a fairly definite train of symptoms—curable, as a rule, by treatment, which is always required when the condition is in the least marked.

Cases falling into the second category—only these cases, with one minor exception, are included in this paper—include those in virgins, in multiparæ, and others, where no evidence of prolapsus is present clinically, although I am aware that in this last group very slight degrees of pelvic descensus cannot always be absolutely excluded. The significance of retroversion in these cases is very difficult to estimate, and many symptoms (e.g., menorrhagia, pain in the back, sterility, &c.) which have in the past been ascribed to it can be explained by associated conditions occurring either intra- or extra-pelvically. With the possible exception of rare cases of sterility due to mechanical difficulty (Giles) and cases included under the "Bonney" syndrome, retroversion itself probably never causes a definite symptomatology, and may, I think, be looked on, when causing symptoms, as an accidental finding associated with other pelvic disorders—e.g., gross pelvic disease such as tubal inflammation, or less obvious pathological conditions such as underdevelopment of the uterus and ovaries.

I cannot, however, agree with Palmer Findlay[1] when he states that retroversion is of no clinical significance, with the possible exception of sterility, save as a step to prolapse; with A. W. Collins,[3] I would rather regard the condition, in acquired cases, as rendering the uterus more liable to disease, exaggerating minor pathological conditions which may be present, and by torsion of the pampiniform veins giving rise to an unhealthy condition of the ovaries, which are frequently prolapsed with the fundus and very tender. In the so-called "congenital" cases any existing symptoms are probably due to associated errors of development—e.g., the posterior cochleate uterus (Blair Bell), stenosis of the cervix, &c.

The era is past of those gynæcologists who considered that retroversion as a uterine displacement was a condition of marked clinical importance always requiring treatment; but this idea, I am sure, is not entirely eradicated from the lay mind, and possibly gives rise to the marked neurotic element in certain cases. The idea is clearly expressed by Palmer Findlay[1]: "For generations women have been led to believe that displacements of the uterus gave rise to all manner of local and general symptoms, and now, when informed by a physician that the 'womb is out of place' they are disposed to rationalise all complaints on the basis of the displacement. Have we not all observed cases in which retroversion gives rise to no pelvic disorder until, through suggestions, the displaced uterus becomes a pain-pathway for neurosis in a woman who has acquired nervous instability from overstress?"

That operative treatment in the past has not always been satisfactory is shown by the numerous operations—I believe they number more than a hundred—which have been devised for the cure of the condition. It is my object here not to extol any one of these or to suggest another, but rather to attempt to estimate the benefit obtained, if any, from some simple abdominal operations, as distinct from the plastic vaginal operations commonly performed. Two varieties of "sling" operation—viz., Kelly's modification of Gilliam, and Mayo's internal Alexander—and a simple method of shortening the round ligaments have been used in the series I am about to describe.

Details of the Cases under Consideration.

The cases in my series were all operated on in hospital between the years 1916 and 1921 inclusive. Their clinical histories were obtained from hospital records, while information as to their present conditions was elicited by means of a written questionnaire of the following nature:—

1. Are you cured by the operation? If not,
2. Were you relieved by the operation, and if so, how long did this relief last?
3. Do you complain of anything now?
4. Have you had a child since?
5. Have you had a miscarriage since?

A request to attend hospital for examination was appended, and over 90 cases were addressed. Answers were obtained from 50; these cases only are included in the series.

State, Age, and Multiparity.—Six of the patients were single; 44 were married, of whom 18 were sterile, including 2 who had had miscarriages only; 26 had borne children. Their ages, in periods of five years, were as follows: Aged 20–25, 6; aged 25–30, 12; aged 30–35, 18; aged 35–40, 8; aged 40–45, 4 aged 45–50, 2.

Symptoms.—The subjective symptoms were as follows, and were rarely single, two or more being usually complained of by the same patient. The duration of symptoms was difficult to estimate, many patients stating that they had "always" had their "trouble," but it appeared to vary between three months and three years. Complaint was made as follows:—

Symptom.	Cases.
Menorrhagia	25
Dysmenorrhœa	21
Constant pain (back or side)	41
Sterility	18
Dyspareunia	3

Operations Performed.

In 19 cases intraperitoneal shortening of the round ligaments was performed, the round ligaments being folded on themselves for half an inch sufficient to render the ligaments tense and hold the fundus

forward in the anteverted position. In the remaining 31 cases sling operations were performed, 10 by Mayo's internal Alexander method, loops of round ligament being withdrawn through the peritoneum opposite the internal abdominal ring, and stitched to the anterior rectus sheath; and 21 by Kelly's modified Gilliam method, loops of round ligament being withdrawn through peritoneum and rectus muscle and joined together beneath the fascia.

In this series of cases other pelvic complications were found in 31, or 62 per cent., of the cases, multiple lesions being present in many instances. They were as follows:—

Symptom.	Cases.
Chronic appendicitis	4
Cystic ovaries	10
Tubal occlusion or inflammation	3
Pelvic or peritubal adhesions	12
Prolapsed cæcum or colon	3
Uterine fibroids	3
T.B. iliac glands	1
Hypertrophied cervix	1

This is a lower percentage of complications than is given by most writers; Palmer Findlay,[1] for example, finds in his series of 480 cases only 20, or 4 per cent., uncomplicated. The difference is due, I think, to my having excluded cases of prolapse as far as possible.

After-results of Operation.

Answers were obtained from 50 patients, of whom 27 attended at hospital for examination and 23 sent written replies only. Ten (or 20 per cent.) expressed themselves as cured, 26 (or 52 per cent.) as relieved, 14 (or 28 per cent.) remained in statu quo. I have labelled cases "cured" when the patients so described themselves or no longer complained of any symptom referable to the pelvis. Where sterility was the only symptom at the time of operation I have not considered the patient cured unless she has since conceived; but where sterility is complained of among several other symptoms, and these other symptoms have all been cured, I have called the case cured.

Information as to relief of individual symptoms has been difficult to obtain, but the following are noted:—

Cases.	Symptom complained of.	Relief obtained in—
25	Menorrhagia	11
21	Dysmenorrhœa	16
41	Constant pain	27
18	Sterility	4
3	Dyspareunia	1

Of the 10 cases who were "cured," complications were present in 8 cases at operation—i.e., 80 per cent. In 26 cases who were only relieved, complications were present in 21, or approximately 80 per cent.; while in the 14 cases who remained in statu quo only 71 per cent. had complications.

Position of Uterus.—In the 27 cases who reported for examination the uterus was found anteverted in 22 cases, of whom 12, or 55 per cent., were relieved, and retroverted in 5 cases, of whom 3, or 60 per cent., were relieved.

Pregnancy had occurred in 8 of the 50 cases, of whom 1 was pregnant at the time of investigation and 2 had had miscarriages only. Of these 8 cases, 6 expressed themselves relieved, while of 4 cases who presented themselves for examination, the uterus was found anteverted in all.

In comparing these results with those of other authors, the difficulty previously alluded to arises—namely, that practically all either include cases of prolapse or leave one in doubt as to whether prolapse is included or not.

In 1899 Alexander[4] published a list of 69 cases operated on by his method of external shortening of the round ligament. In practically all cases a pessary, either a Hodge or a Hodge and stem, was inserted at the time of operation, and nine cases required operation for prolapse. He reports on cases at intervals from six months up to ten years after operation and finds the uterus in good position in 46 cases and the symptoms relieved or cured in 36 cases. Pregnancies had followed in 18 cases, of whom 13 remained well, and among whom the uterus was found anteverted in all but 3 cases. A series of cases published by A. Goldspohn[5] is also interesting; of 127 cases treated by a modified Gilliam operation (perineal operations were also required in 23·5 per cent. of cases) health and position of uterus remained good in 88 per cent. of cases. In 1·6 per cent. of cases there was a recurrence of displacement.

Comparing the above series of results with those obtained by pessary treatment I note that F. W. Lynch[6] in a series of 281 cases found a pessary useless in 47 (a pessary could not be retained in 32 cases), but in the remainder obtained a 72 per cent. cure. These results appear much more satisfactory than those recorded in my series, but I recapitulate that I consider this due to the inclusion in their series of well-marked cases of prolapse.

Conclusion and Summary.

1. Cases of retroversion complicating prolapse should be treated as cases of prolapse. Abdominal operation alone rarely, if ever, cures these cases, and their inclusion in statistics of operations for retroversion leads to confusion.

2. Retroversion is not a disease in itself and never, with the possible exception of the "Bonney syndrome," gives rise to a definite train of symptoms. It is usually complicated by other pathological findings; and it is these, as a rule, which indicate operative treatment, and upon which relief of symptoms largely depends. In this series, 80 per cent. of "cure" cases were complicated, while only 70 per cent. of cases unrelieved had complications. Possibly a longer series might show a more marked difference between these two. In cases where no complication is found on clinical examination, and sterility is complained of, operation is sometimes indicated, as closed tubes may be present and a better chance of conception seems to be given after dilatation of the cervix, if the uterus is replaced and retained in the anteverted position.

3. In many cases an undoubted nervous element is present, the significance of which must be carefully assessed before operative treatment is undertaken, and in considering the result of such treatment.

4. Too few cases of pregnancy have occurred in my own series to enable one to make any statement as to its effect, but from a consideration of the results given by other authors, pregnancy does not seem to exert any deleterious effect on orthopædic and clinical results of treatment beyond the fact that it makes prolapsus more common and may, if symptoms recur, transfer the case to one of the first category mentioned in this paper.

All cases mentioned in this paper were patients at the Hospital for Women, Soho-square, and I desire to express my thanks to members of the honorary staff for allowing me to make use of notes, &c.

PEOPLE'S LEAGUE OF HEALTH.—The next course of the Sims Woodhead series of ten weekly lectures, followed by an examination (not compulsory), and Travelling Scholarship Prize awards, will be given at the Medical Society of London, 11, Chandos-street, Cavendish-square, London, W., beginning on Feb. 11th, at 6 P.M. The lectures will be delivered by Dr. H. A. Harris, Prof. M. S. Pembrey, Sir Frederick Mott, F.R.S., Sir Harry Baldwin, Prof. J. C. Drummond, Dr. J. Mellanby, Sir William Arbuthnot Lane, Prof. H. R. Kenwood, Mr. E. B. Turner, and Dr. A. F. Tredgold. Further particulars may be obtained from the hon. organiser of the League, 12, Stratford-place, London, W. 1.

ROYAL SOCIETY OF MEDICINE.

SECTION OF COMPARATIVE MEDICINE.

DISEASES OF NUTRITION IN ANIMALS.

A MEETING of this section was held on Jan. 23rd, Sir LEONARD ROGERS presiding.

Prof. E. MELLANBY pointed out that in recent years our views on nutrition had greatly changed. It was now known that substances formerly regarded as physiological units had great biological differences—for example, different proteins, and, moreover, dietetics had been altered by the discovery of vitamins. The deficiency diseases—scurvy, beri-beri, and rickets—could all occur in the animal as well as in the human world. Scurvy had been described in hogs and occasionally in dogs. Veterinary text-books consulted by Prof. Mellanby recommended the addition of grain, acorns, and horse-chestnuts to the diet of hogs thus affected; these substances were not strongly antiscorbutic. Beri-beri was sometimes to be seen in domestic animals, such as birds, and was easily cured. He intended to discuss chiefly the conditions which in animals tend to produce good and bad bones. Actual rickets did not indeed often appear spontaneously in animals except dogs, but while bone changes might not be produced, the lowered vitality and changes in muscle resulting from bad feeding might well be of economic importance in other animals. There were some grounds for assuming that the results of his experimental work, which had been done on dogs, might apply to other animals, even herbivorous ones, in that green food, such as lucerne and clover, here supplied the necessary accessory factor.

The Toxic Effect of Cereals.

One of the commonest dietetic mistakes was to feed animals with cereals—for example, oats or bran. Prof. Mellanby demonstrated slides showing that dogs fed on a diet deficient in vitamin A, leading to rickets, got worse when fed on cereals, white flour being least toxic, and next in order being rice and rye; oatmeal and wheat-germ were specially liable to intensify the rickety condition. The toxic factor could be associated neither with the calcium-phosphorus ratio in the foodstuff, the salt content, the carbohydrate present, nor the nucleic acid; its nature was still undiscovered, and it could only be said at this stage that something in cereals was toxic and interfered with the process of calcification. The antagonists to this unknown factor included (1) calcium (carbonate being better than phosphate); (2) ultra-violet light when the diet was not excessibly deficient; (3) cod-liver oil, of which $\frac{3}{4}$ daily counteracted the detrimental effect even of oatmeal. Prof. Mellanby showed slides not only of bone but of teeth and of muscle, to show the damage that could be done by a cereal diet. The first result of such a diet was lethargy, which might go on to paralysis; it was easy to produce any intermediate stage by varying the diet. He suggested that in animals put out to graze the rest was not so important in their cure as the plentiful green pasture available. Incidentally the diet generally given to racehorses in training was puzzling, as on theoretical grounds it seemed unlikely to produce fast runners.

Whether his results applied to animals other than dogs Prof. Mellanby could not state definitely, but the evidence that they did apply to children was convincing. The points that required emphasis from the veterinary standpoint were: (1) That the foodstuffs in general use had a toxic effect; this was no reason for not using them, but the fact should be realised and antagonists suitable for different animals—lucerne, cabbage, milk, fish fats—should be added. (2) That calcium carbonate was a serviceable antagonist. (3) That freedom in fields, which implied greenstuffs and sunlight, was of benefit. Animals kept in confinement and fed on oats or oatmeal or wheat-germ were in some danger. Progressive agriculturists who gave their stock wheat-germ because it contained vitamin B and some vitamin A must remember that it contained also something of a toxic nature.

The Development of the Science of Dietetics.

Miss HARRIETTE CHICK, D.Sc., traced the history of the newer dietetics during the last ten years, showing how the parallel between polyneuritis of birds and beri-beri, and that between scurvy in guinea-pigs and in humans, and rickets in dogs and in humans, pointed to the conclusion that many of the results of experimental work did apply to the whole race of mammals and sometimes to birds also. Work done piecemeal at different places and times appeared to be coalescing slowly into a coherent intelligible whole. Quite recently American investigations on poultry had shown that on a diet deficient in vitamin A, leg weakness and a diseased condition of the eye similar to that seen in the rat and rarely in infants occurred in fowls, and the interaction of light and diet, proved on children in Vienna, had also found a complete parallel in these animals. The only animal which still appeared anomalous in this respect was the pig, but Miss Chick expressed the hope that ultimately even the pig would be brought to heel! As an instance of a striking anomaly that had been explained by further research, Miss Chick recalled the disconcerting failure to cure guinea-pigs of scurvy with lime-juice, and its explanation by the history of the change of nomenclature of lime-juice and lemon-juice.

The Veterinary Point of View.

Mr. HENRY GRAY said that no practical man would ever think of feeding dogs on the food Prof. Mellanby had used in these experiments. Rickets could be induced in dogs, especially in large breeds, if they were kept on a chain and given no exercise. Practical agriculturists fed their animals on the food produced on farms, guided by tradition handed down and modified by their own experience. Osteomalacia could occur in animals exposed to sun and given green food; it appeared sometimes to be dependent on the change of food natural to a special race. For example, horses accompanying the French army to Cochin China developed osteomalacia, and fodder had to be imported for them from Europe and Algeria. He considered heredity to be a factor in bone disease, and also overwork. He had seen rickets develop in dogs kept without exercise in sunlight, and had seen horses in good condition after 20 years in coal-mines. Certain breeds of toy spaniels were liable to mal-development of bone, also bulldogs, in which teeth were sometimes set in cartilage; this seemed to be a heredity defect. Lack of muscular power in shire horses was the result of over-forcing and lack of exercise. Mr. Gray concluded, after studying Prof. Mellanby's interesting conclusions, that "his theory was not applicable to our practice."

Polyneuritis and Beri-beri.

Colonel R. MCCARRISON wished to dissent from the general impression that polyneuritis of birds was identical with beri-beri. In man suffering from beri-beri cardiac enlargement was a prominent feature, while in experimental birds with polyneuritis atrophy of the heart was found. He had produced polyneuritis some 2000 times, and not until among the last 200 pigeons had he met with true beri-beri—with enlarged heart, pericarditis, and so forth. This batch of pigeons came from Bangalore, and five or six out of the 200 were affected. As regards beri-beri in man, in 1917 two battalions of the same regiment were quartered at Quetta and fed from different sources. Of the 800 fed on rice 3·5 per cent. developed beri-beri—approximately the same percentage as of the pigeons. Colonel McCarrison expressed his conviction that something more than the absence of vitamin B was necessary for the production of true beri-beri in birds—some factor with a

specific action on the heart. In India, where rice was cultivated everywhere, of the 595 cases occurring in the Indian army between 1900 and 1914, 500 occurred in an area in the north-east, where beri-beri is endemic. It would seem that residence in a certain locality imparts some stigma to individuals which makes them more liable to succumb to bad dietary conditions. With regard to muscle, if the changes shown by Prof. Mellanby in skeletal muscle took place, muscles of gastro-intestinal tract were probably even more affected by deficient diets and faulty feeding might well account for the large amount of chronic gastro-intestinal disease now so common. As to the importance of faulty feeding in resistance to infection, Colonel McCarrison quoted his experiments on monkey carriers of *Entamœba histolytica*—those only who were badly fed developing dysentery.

Prof. G. H. WOOLDRIDGE pointed out that in animal dietetics the economic aspect often overshadowed the medical one, even in standard text-books. He emphasised the need of balance as well as vitamins in food. Affections allied to rickets occurring later in life had been studied. Sir Arnold Theiler in South Africa showed that cattle with depraved appetites who ate bones of carcasses left on the veldt acquired a bone disease; this was partly due to infection by bacteria, since when these bones were sterilised and the animals induced to eat them no bad effects resulted.

Dr. M. J. ROWLANDS confirmed Prof. Mellanby's remarks as to the toxic effect of wheat-germ from practical experience. On theoretical grounds he had tried to feed pigs with wheat-germ as a source of vitamins A and B; 20 large white sows had been given wheat-germ, supplemented by meat and fat; all had developed violent diarrhœa. Ten had been put on middlings and recovered, and the 10 controls left on the old diet had died. He agreed with Mr. Gray that the diet used by Prof. Mellanby was unsuitable for ordinary dogs, but of the importance of the effect of vitamins on animal nutrition he was convinced by the happy practical results of their administration.

Captain KIRK asked whether the question of disturbed internal secretions as a factor in rickets had been considered by Prof. Mellanby. He asked whether any light could be thrown on the fact that if the rations of hard-working horses were not reduced during a period of rest they were liable to develop acetonuria.

Dr. F. W. COLLINGWOOD said that pigs had been reared successfully on nothing but swedes, with no meat at all.

Prof. F. HOBDAY confirmed the fact that osteomalacia appeared to be endemic. In veterinary experience crude cod-liver oil seemed to give better results than the purified form, and calcium lactate appeared to be the most useful form for administering calcium.

Captain F. C. GILLARD suggested bowel parasites as a contributory factor in rickets.

Dr. J. S. EDKINS pointed out that cats were specially liable to parasites, but did not suffer from rickets.

Reply.

Prof. MELLANBY, in reply, explained that theories such as those of hormones and bowel parasites as factors in rickets appeared to be merely hypotheses with no evidence to support them, whereas experimental evidence, though it might not be conclusive, represented at least an attempt to pick out the more important factors in the production of this disease.

SECTION OF PATHOLOGY.

A MEETING of this section was held on Jan. 15th, Prof. J. G. LEDINGHAM, F.R.S., the President, being in the chair.

Dr. J. KILIAN CLARKE contributed a paper on the

Bacteriology of Dental Caries.

He said that all the very meagre evidence at our disposal tended to support Miller's theory that dental caries is due to bacterial fermentation of carbohydrates with production of acid which decalcifies the teeth. Of late considerable attention had been directed to the acidophile group of bacilli in this connexion; the members of this group were active producers of acid, in a high concentration of which they could live—in fact, they grew best in a medium of a comparatively high acidity. McIntosh, James, and Lazarus-Barlow isolated acidophile bacilli from 44 out of 50 carious teeth examined by them, and produced lesions resembling caries in healthy teeth placed in glucose broth cultures. The teeth examined by these observers and others were in a fairly late stage of caries, with cavity formation, and the conditions in these cases are very different from those which obtain at the initiation of the lesions. Dr. Clarke was unable to isolate acidophile bacilli from early cases in which there was little or no apparent loss of enamel substance, but found another organism constantly present; this organism does not appear to have been described previously, and he proposed the name *Streptococcus mutans* for it. *S. mutans* is a streptococcus on media of a neutral reaction, but grows as a bacillus if the reaction becomes acid. It is Gram-positive, aerobic, and facultatively anaerobic. The colonies are very coherent and difficult to pick up off the surface of the medium, as they run along in front of the needle. It is an active producer of acid, but is not acidophile, as it is quickly killed if the medium becomes acid, and refuses to grow on a medium with a reaction more acid than pH 5·6. All strains isolated are identical in fermentation and agglutination reactions. *S. mutans* was isolated from 36 out of a series of 50 teeth (in pure culture from eight), while in most of the negative cases colonies of the organism were seen, although it could not be isolated. The lesions in these teeth were, in the great majority of cases, very early. Acidophile bacilli were isolated only in the more advanced cases, where there was a break in the continuity of the enamel, or in cases in which the lesions were very shallow and the surface encroached on in taking the specimens. Attempts to produce artificial caries in healthy teeth, by placing them in cultures of *S. mutans*, were being made. The growth of the organism adhered markedly to the surface of the teeth and decalcification of the enamel took place with comparative rapidity. Decalcified sections of a tooth kept in cultures for nine and a half weeks were exhibited; they showed the organisms, which had penetrated the enamel, invading the dentinal tubules. The medium had been changed daily, so that the tooth did not remain for any length of time in an acid solution; in McIntosh, James, and Lazarus-Barlow's experiments the medium was changed only once a week. Although there was as yet no conclusive evidence to prove that *S. mutans* was the cause of caries, the facts that it was found regularly in early cases, sometimes in pure culture, grew best at a reaction approximating that of the saliva, adhered to the surface of the enamel, and could produce lesions in vitro similar to those of caries were, to say the least, suggestive.

Mr. ROBERT T. GUNTHER demonstrated a case of

Arterio-sclerosis in a Crocodile of the Mesozoic Age.

He exhibited vertebræ of fossil crocodiles from the mesozoic strata of Oxfordshire which showed coloured Y-shaped markings following the course of segmentally arranged intercostal arteries and veins. The suggestion receives confirmation from the subsequent finding of such arteries in a recent crocodile and from the discovery of lateral grooving of similar vertebræ in a crocodile from an older geological stratum. That the imprints of these arteries, whether in colour or as grooves, had not been previously observed, is due to the great scarcity of specimens exhibiting them, and as by far the greater number of crocodilian vertebræ did not show them Mr. Gunther is inclined to regard them as pathological, and possibly as indicating an early stage of arterio-sclerosis.

Mr. ALEXANDER FLEMING read a paper on

Accuracy of Measurements with Capillary Pipettes.

He described the various types of error which might occur and showed that when the "wash,"

that is, the fluid which remains adherent to the pipette, is eliminated a volume of fluid as small as 5 c.mm. can be measured from a capillary pipette with great accuracy. The "wash," which is the greatest error in measurement with capillary pipettes graduated in the ordinary way with a measured volume of mercury, is almost constant when the fluid is expelled from the tube at anything approaching the same rate of speed, and with pipettes such as are in common use it amounts to about 3 per cent. of the total volume. The "wash" provides a progressive error in making a series of two-fold dilutions such that at the eighth dilution the error will amount to about 13 per cent. The author described a pipette graduated in such a manner that a series of dilutions in arithmetical or geometrical progression could rapidly be made with accuracy and the error due to the "wash" eliminated.

SECTION OF OPHTHALMOLOGY.

A MEETING of this section was held on Jan. 11th under the presidency of Mr. A. L. WHITEHEAD.

Lieut.-Colonel H. HERBERT read a paper on a case of

Late Chronic Sympathetic Ophthalmia.

He said the disease followed a trephining operation, performed without iridectomy, for congestive glaucoma, in November, 1917, when the patient was 62 years of age. More than five years elapsed before the other eye became involved. The operation did not entirely relieve the tension, and the congestion persisted for more than a month. After that it gave no more trouble until the fellow eye was attacked, and then injection and tenderness returned. In the sympathising eye the disease was comparatively mild, and seemed to yield completely to three months of simple mercurial treatment. In this case there was ample histological evidence that the operated eye, during the five quiet years, was only relatively quiet. The notes mentioned only a dense white pupillary opacity and the fact that the eye was blind. There was good reason for believing the eye was the seat of a very feebly progressive infective process throughout. The nodular character of the uveitis was very noticeable, the foci of greatest infiltration standing out as round white points in the iris, ciliary body, and choroid. Colonel Herbert described the cytology by means of a number of slides. As a probable indication that the unknown specific organism had become acclimatised outside the uvea, large-celled infiltration could be followed through the tissues filling the trephine hole and through the sclera, along the anterior perforating blood-vessels above and below the cornea. It had spread into the conjunctiva, and backwards immediately superficial to the sclera. There was another extra-uveal site of activity beneath the thick pupillary membrane noticed clinically between the membrane and a thick capsular cataract. The detached retina was folded and thickened, and the ciliary body and choroid were more or less detached from the sclera, and their layers were widely separated. The inner surface of the choroid below merged into a thick layer of new fibrous tissue, containing masses of pigment granules, derived possibly from the retinal pigment layer; pigment had also wandered into the detached retina.

With regard to the bearing of the case on the operative treatment of glaucoma, he had not heard of any instance of the disease following an intentional iris-inclusion operation for over 20 years, and he believed a correctly performed iris-inclusion operation was quite free from this risk; but he held that correct performance included effective conjunctival antisepsis. In the present case the trouble was probably due to the lack of this.

Discussion.

The PRESIDENT said that most of those who habitually did the trephine operation would join issue with Colonel Herbert's contention that in most cases there was incarceration of the iris.

Mr. R. PICKARD spoke of a case he had three years ago which might have been one of sympathetic infiltration after trephining. The operated eye did not do well, and about six weeks later keratitis punctata developed in the fellow eye. He promptly removed the first eye, and the other recovered. He had had two or three cases of chronic glaucoma affecting both eyes, in which suddenly, for no apparent reason, one eye developed severe irido-cyclitis, leading to blindness. It looked very much like sympathetic ophthalmia. He thought that in some cases chronic glaucoma was the expression of some very mild cyclitis without the ordinary symptoms of cyclitis. Yet it might be seen when there had been no operation on the other eye.

Sir WILLIAM LISTER said that in doing the trephining operation it was very important to see that no iris whatever was incarcerated. He believed that the cases of late infection which had occurred were those associated with some entanglement of iris in the wound. This avoidance of incarceration of iris should be aimed at by three procedures. Directly the knuckle of iris appeared through the trephine hole, the posterior portion should be pulled up so as to do irido-dialysis, and pull out sufficient iris, so that when the iris was cut it spread away from the opening. Where there was a large pupil one should aim at doing a complete iridectomy right through to the pupillary margin.

Mr. R. A. GREEVES said that sometimes the trephine was put on too far back, resulting in incarceration of the iris. He had cut sections of a series of eyes which had been trephined and were failures, in each case because of iris incarceration, and in all of them he considered the trephine had been put too far back and the cornea had not been split far enough forward.

Mr. R. L. REA spoke of a case in which he had to trephine two eyes in an urgent case of glaucoma. In one case the iris became incarcerated round the edge of the trephine hole and he could not free it. Therefore as soon as the flap was replaced he put atropine in the eye, and kept it under the influence of that drug. It drained very well, and he saw the iris pull away completely in a fortnight. The eye had now done well, and vision was restored to 6/9 partly.

The PRESIDENT agreed with Sir William Lister as to the importance of securing freedom of the iris from the wound. He would do complete iridectomy rather than leave the slightest trace of iris in the trephine opening.

Colonel HERBERT, in reply, agreed that the small incarceration of iris had a good deal to do with the disease in this case. There was no doubt in his mind that it was a case of sympathetic ophthalmia. The histology was characteristic: there was nodular uveitis, and it was different from the tuberculous or syphilitic case.

Mr. T. HARRISON BUTLER read a paper on the

Practical Value of the Slit-Lamp,

and demonstrated the lamp. He said many still had the idea that the slit-lamp was useful chiefly for research, but such was not the case. It enabled problems connected with the ocular fundus and the media to be studied afresh, not only by greatly increased magnification, but by permitting the illumination of structures from behind, and enabling the anatomy of the eye to be seen in optical section. By means of a 40-candle half-watt gas-filled lamp a ray of light could be directed into the eye and the cornea could be seen to be illuminated, the anterior chamber dark, and in lens sclerosis there were seen in the lens dissociation areas. By lens light one could see holes and atrophic areas in the iris collarette. Also, the circulation in the vessels at the limbus in the normal eye could be seen. During the four months he had worked with the lamp, he had learned much about the anatomy and pathology of the exterior segment of the eye. The examination must be made in complete darkness, and the more difficult

objects could be seen only when the eye was dark-adapted. The examination of patients with the lamp caused them little or no discomfort. Cases of interstitial keratitis were unsuitable for examination by this means. The slit-lamp did not supersede present methods, but amplified and supplemented them. The depth to which foreign bodies had penetrated the cornea could be correctly estimated by using the lamp, and means for removal could be taken accordingly. It was of especial value in inflammatory conditions of the cornea. Deposits of cells on the endothelium in keratitis punctata could be detected when the particles were too small to be seen with the naked eye. A case of interstitial keratitis could not be completely interpreted without the slit-lamp. Observation of the aqueous was very difficult, and called for complete dark adaptation. The presence of cells in the aqueous was the first sign of irido-cyclitis, and was especially valuable in the case of a sympathising eye; such cells when seen could be regarded as an early warning of the onset of sympathetic ophthalmitis. The slit-lamp was of most service in examining the lens. The optical section given by the narrow ribbon of light enabled the lens to be seen in profile. Vogt had differentiated as lens regions the capsule, the cortex, the senile nucleus, and the embryonic nucleus. Clinically, the lens could be regarded as three lenses, one within the other, and these gave mirror effects to focal illumination. In a case of diabetic cataract Mr. Butler noted that the lens capsule was greatly thickened, and in such a case, if it came to operation, he would use capsule forceps in preference to a capsulotome. He showed four photographs illustrating a case of combined cortical cataract and nuclear sclerosis. Examination of the lens in mirror light showed that the whole surface was covered with nipple-like eminences. One of the chief uses of the slit-lamp was the power it gave to recognise slight signs of cyclitis. The chief drawback to its use was the extra time required for examination, some 50 per cent. longer than for the older method. The new means of examination was so important and specialised that the formation of a small society of slit-lamp enthusiasts was justifiable, to meet and discuss cases and problems and for mutual education.

Mr. BASIL GRAVES spoke of the many clinical features which were revealed by the slit-lamp, and the fact that it enabled the observer to detect prodromal manifestations of sympathising ophthalmitis at a far earlier stage than had been possible before its introduction. An apparently normal senile eye stood revealed by this instrument as a veritable museum; and its use in the case of patients known to be suffering from some regional affection was very fruitful of results. It was a remarkable instrument for conducting research into eye conditions, and he mentioned a number of respects in which this was the case, and the precautions which needed to be observed. But it should only bear its due and proportional share in the scheme of routine clinical examination.

SECTION FOR THE STUDY OF DISEASE IN CHILDREN.

Exhibition of Cases and Specimens.

A MEETING of this section was held on Jan 25th, with Mr. R. H. ANGLIN WHITELOCK, the President, in the chair.

Dr. GEOFFREY EVANS showed a case of

Interstitial Nephritis Simulating Diabetes Insipidus

in a girl aged 13. The child's health had been good until four years ago, when thirst, polyuria, and loss of weight began. On account of these symptoms a diagnosis of diabetes insipidus had been made at two general hospitals, but the diagnosis of interstitial nephritis was established after her admission to St. Bartholomew's Hospital by the low specific gravity of the urine and the presence in it of red and white blood cells and a trace of albumin, and by the deficient urea secretion and the high blood-urea content. Cases of interstitial nephritis in children were of two types: (1) where the renal condition was a part of a diffuse hyperplastic sclerosis; and (2) where the only changes were in the kidneys. He thought this case was of the latter type and probably had a congenital kidney defect (possibly only one kidney).

Dr. C. WORSTER-DROUGHT exhibited a case of

Juvenile Tabes Dorsalis

in a girl of 10 years, with a case of Friedreich's ataxy for comparison. Tabes dorsalis was very rare in childhood. In 1903 Marburg collected the records of 34 cases but some of these were doubtful, as the difference between this disease and Friedreich's ataxy was not always appreciated by the earlier observers. In the juvenile form of tabes the pupillary signs were the first to appear and might be followed by optic atrophy; lightning pains and visceral crises were less common than in the adult form, and ataxy was absent as in the case shown. Again, juvenile tabes was commoner in the female sex. On the other hand, Friedreich's ataxy was marked by an absence of pupillary signs and the presence of ataxy; loss of the knee- and ankle-jerks was common to both diseases.

Mr. O. L. ADDISON showed a specimen of the spleen from a case of

Gaucher's Splenomegaly.

The spleen, which was removed under the impression that the child was suffering from splenic anæmia, was much enlarged and paler than normal and exhibited no capsular thickening. The glands at the hilum were enlarged; the viscus weighed 17 oz. and the weight of the child from whom it was removed was 19½ lb. The child recovered from the operation.—Dr. HAROLD PRITCHARD said the child was admitted to his wards during an attack of bronchitis. Systematic examination revealed enlargement of the liver, very great enlargement of the spleen as far as the umbilicus, and no enlargement of lymphatic glands. There was anæmia of the chlorotic type and leucopenia with a relative leucocytosis. The Wassermann reaction was negative. The true nature of the disease was only revealed by the microscopic examination of the excised spleen which showed the typical Gaucher's cells. Since the operation the child had appeared more contented; previously it had been very fretful. Gaucher's splenomegaly was apparently a very rare disease as he (Dr. Pritchard) had only been able to find 23 cases recorded in the literature.

Dr. PARKES WEBER said it was clear that Gaucher's disease was one of the whole reticulo-endothelial system and affected the endothelial cells of the liver and bone-marrow as well as those of the spleen. These cells were distended with a lipoid substance. Dr. McNee had demonstrated to him in sections of this spleen, which was an excellent example, that the bright lipoid substance was not doubly refracting and hence it could not be, as had been supposed, a cholesterin ester. The disease was evidently an inborn error of metabolism resembling alkaptonuria, hence its familiar occurrence.—Dr. J. W. MCNEE thought that Gaucher's disease was not so rare as had been supposed, for he had seen three cases in this country since the war. This specimen showed the lipoid in the cells better than any other he had seen. While the nature of the lipoid remained unknown it seemed in many ways to resemble the substance found in amyloid disease. Dr. A. K. GORDON pointed out that the characteristics of Gaucher's cells were not made visible by the methods ordinarily employed for staining sections. If frozen sections were stained with Giemsa's stain every stage in the formation of the Gaucher's cell from the lymphoidocyte could be observed.—Dr. F. J. POYNTON inquired whether the diagnosis of Gaucher's disease could be made during life and whether the operation of splenectomy was likely to improve the prognosis.—In reply, Mr. ADDISON said that in recorded cases splenectomy had not influenced the course of the

disease, and Dr. H. PRITCHARD added that the disease had on occasion been diagnosed by splenic puncture.

Mr. B. WHITCHURCH HOWELL and Dr. W. L. KINNEAR showed a case of

Fragilitas Ossium with Blue Sclerotics.

The patient was a girl, aged 3½, who had already suffered six fractures. The mother, who also exhibited blue sclerotics, had had fractures of the clavicle, wrist, radius and ulna, and humerus. The case was shown with a view to obtaining suggestions as to treatment. Dr. Kinnear said that there were only two cases of fragilitas ossium in the family and (in reply to Dr. Parkes Weber) that there was no family history of deafness. On an analogy with rickets he intended to try the mercury quartz-lamp treatment and possibly parathyroid medication.—Dr. A. FEILING considered that the disease was a general one and pointed out that the liability to fractures persisted after puberty. No treatment was known to avail.—Dr. HELEN MACKAY thought that the mercury vapour lamp was unlikely to be beneficial since its effect in rickets was that of cod-liver oil, which was known to have no effect in fragilitas ossium.—Dr. ERIC PRITCHARD had seen a case of multiple fractures do well with cod-liver oil and the mercury lamp treatment.

Dr. ERIC PRITCHARD showed a case of

Anæmia in a Premature Infant treated by Intraperitoneal Injection of Blood.

The technique of the injection was quite simple; the abdominal wall was either punctured with a blunt needle which would not injure the gut or a sharp needle was used to transfix a "pinched-up" fold of the abdominal wall.—Dr. IZOD BENNETT asked whether there was any evidence that red blood cells injected into the abdominal cavity reached the circulation, and Dr. GORDON pointed out that the result of injecting blood into the peritoneum was to produce an extravasation of phagocytes which rapidly ate up the red blood cells. He suggested that the child was suffering from some infection and that the benefit it had obtained, apparently from the injection of blood, was in reality due to the peritoneal reaction produced.—In reply, Dr. PRITCHARD admitted that it was difficult to see how the red blood cells gained access to the circulation.

Dr. W. E. HILLS showed

A Child in whom the Sex has not yet been Determined.

The PRESIDENT thought the child a boy, who exhibited an extreme degree of hypospadias.—Dr. POYNTON discussed two similar cases he had seen, and Dr. DONALD PATERSON said that cases which had been "opened" to determine the sex almost invariably proved to be males.

Dr. IZOD BENNETT showed a girl who exhibited

Choreiform Movements Persisting for Four Years.

The movements began after an attack of somnolence lasting 24 hours, and were treated initially with ice-packs with the result that the movements disappeared and a flaccid paralysis occurred which lasted two months. After a short interval, during which the child appeared normal, the movements returned. He had regarded the case as probably one of encephalitis lethargica, but one member had suggested that the movements were functional and might be cured by suggestion.—Dr. E. PRITCHARD and Dr. A. W. CARR agreed with Dr. Bennett's original diagnosis.

Other Cases.

Dr. R. C. JEWESBURY showed a case probably of retroperitoneal sarcoma in an infant with a swelling of the left side of the back which had grown visibly since December, 1923.

Dr. ERIC PRITCHARD showed a case of chronic interstitial nephritis in a child aged 8 months. Originally the child had been sent to Mr. Tyrrell Gray and Dr. D. Paterson as a case of vomiting thought to be due to congenital hypertrophic stenosis of the pylorus, but the true nature of the case was revealed by the low urinary urea output and the high urea content of the blood.

Mr. WHITCHURCH HOWELL showed a case exhibiting a local atrophy of muscle and subcutaneous fat affecting chiefly the right lower extremity. The child exhibited was the second child of first-cousins; the elder child exhibited no abnormality beyond slight albinism.—The case was discussed by Dr. PARKES WEBER, who pointed out the fibrous nodules over the shin. A number of similar cases where the upper limb was affected had recently been described and labelled "lipodystrophia progressiva" of the superior type.

Dr. BERNARD MYERS read a paper on methods of collecting records of sick children, and described a method of collecting statistics which had already been put into operation.

LIVERPOOL MEDICAL INSTITUTION.

A MEETING of this institution was held recently, Prof. J. HILL ABRAM, the President, being in the chair.

Dr. D. R. OWEN read a note on a case of

Abdominal Aneurysm.

Aneurysm of the abdominal aorta had occurred, he said, in a man previously in good health. A week after an attack of pain in the back diagnosed as lumbago he was sent into hospital with shock, distension of the abdomen, and tenderness, but there was no rigidity and no vomiting. At first it was thought there was a tumour in the region of the sigmoid and pancreatic disease was considered, although there was no glycosuria. The attack of pain subsided and an expansile tumour of the abdominal aorta was then clearly felt. One day later, and three days after the acute attack, the patient had another acute attack, collapsed, and died. Autopsy showed clots of varying duration in a retroperitoneal collection of blood from a rupture of a diffuse aneurysm about two inches above the iliac bifurcation. There was extensive ulceration and calcification of the aorta, and the leaking of the aneurysm probably accounted for the attacks of pain. The first acute pain occurred whilst lifting a weight when at work, and gave the case a forensic as well as a clinical interest, in that when admitted the case resembled an acute abdomen. The only treatment given was the intramuscular injection of saline containing horse serum, and the general treatment of shock.

Dr. ROBERT COOPE read a short paper on

Some Points in the Diagnosis of Pancreatic Disease.

After dealing with the difficulties of diagnosis he discussed briefly the acute and subacute lesions of the pancreas and their clinical features. Concentrating more particularly upon chronic disease of the gland, for example, scleroses of various types, and cancer, he mentioned certain helpful points in diagnosis which could be drawn from a consideration of its anatomical situation, its physiological functions, and the association in certain cases of similar trouble in the liver. The clinical picture of chronic pancreatic trouble was then discussed and a critical review was made of the various tests of pancreatic function. In Dr. Coope's experience it was rare in chronic pancreatic disease to get a marked excess of neutral fat in the fæces. In cases with excess of fat this was usually present as split fat and associated with blockage of the bile-duct. Loewi's adrenalin mydriasis test was unsatisfactory, as it was sometimes misleading in cases of gall-stones without any obvious pancreatic involvement. The diastase content of the blood and urine was usually normal or low, and therefore of little help. A helpful and simple finding was the presence in the fæces, under certain strictly controlled conditions, of marked striation of all the muscle fibres seen under the microscope. It was probably the putrefaction of this undigested muscle fibre which gave the intense

indoxyluria seen in many of these cases. Glycosuria was comparatively rare, a finding not surprising in view of the pathology of conditions causing blockage of the duct. Dr. Coope had had no experience of the examination of the ferments obtained by duodenal intubation, but mentioned Carnot's results, and his view that lipase is the most satisfactory ferment to examine from the point of view of diagnosis of pancreatic insufficiency.

Dr. H. S. PEMBERTON submitted some observations on the

Action and Therapeutic Value of Insulin.

After an account of its properties the in vitro action of insulin on glucose was discussed. Five theories of activity in the living organism were considered, stress being laid on the glycogen-forming view, in favour of which experimental work by Dr. L. Cunningham and the speaker in frogs on galactose curves in the blood and on the differences in glucose content of arterial and venous blood in normal and diabetic conditions was described. The paper concluded with some pessimism as to the permanency of betterment in the diabetic as a result of insulin exhibition, but with acknowledgment of the advance which insulin had caused in the study of carbohydrate metabolism.

Dr. A. G. GULLAN stated that he had found insulin with restricted diet very effective in cases of severe diabetes in young adults. Several of these cases had the insulin gradually reduced and were now sugar free for a considerable time after insulin was stopped, but of course their diet was a restricted one. He also mentioned an interesting case in an older man where chronic pancreatitis had been noted by a surgeon when performing an operation for infective cholecystitis; the patient had later developed diabetes, and had done extremely well with treatment by insulin when other methods of treatment had not been satisfactory.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF STATE MEDICINE.

Discussion on the Diploma of Public Health.

A MEETING of this section was held in the Royal College of Physicians of Ireland on Jan. 11th.

Dr. N. M. FALKINER read his presidential address, in the course of which he reminded the meeting that the first paper read before the section was by Dr. Thomas W. Grimshaw, Registrar-General, on Feb. 9th, 1883, under the presidency of Sir Charles Cameron, and that of the original council Sir John Moore still survived. In due course many valuable papers had been contributed adumbrating the statutory enactments which were ultimately passed and showing that the profession in Ireland had performed its duty in forwarding legislation in public health during the past 40 years. The President went on to discuss the status of the Diploma in Public Health, reviewing the proceedings of the General Medical Council since the year 1869 in this regard. The University of Dublin had established a Diploma in State Medicine in the year 1870. The name of Prof. William Stokes was notably connected with this achievement. The President suggested that the subject should be discussed under the following headings: (1) uniformity in education and examinations; (2) uniformity in nomenclature of degree granted; (3) formation of a State public health service, (4) a combination between the Irish universities and colleges for instruction and examination in public health qualifications; (5) the status of preventive medicine in preliminary medical education.

Sir EDWARD COEY BIGGER mentioned some Acts of Parliament which had been passed in the years 1913 to 1920 in the interest of public health. These included Acts relating to the notification of tuberculosis, provision of meals for school-children, notification of births, venereal diseases, the Ministry of Health, and the enactments for the registration of nurses and midwives. He described the steps which led to the new regulations for the Diploma in Public Health in 1920. He had visited two universities to inspect some examinations for this degree and had found that the instruction in them for this examination was far from being uniform. Later, the new rules which were at present in force were started. He was of opinion that no medical officer would be as proficient as he should be unless he had some knowledge of clinical medicine. This would enable him to deal with the difficulties of a general practitioner in a more sympathetic way. When the course of study for the D.P.H. had been lengthened from nine to 12 months it was decided that the amount of time which had previously been spent on the study of practical chemistry was not necessary, although, of course, it gave the students a good scientific training. However, the chemistry course was shortened and the bacteriology course was lengthened. Some were of opinion that the rules in connexion with this examination were now too stringent, but he personally thought they were not. Some time later on it might become necessary to have a modified examination in connexion with the public services.

Sir JOHN MOORE said that the question of nomenclature for the qualification of D.P.H. was provided for by Act of Parliament. In this Act there were three names given for it—State medicine, public health, and sanitary science. On and after Jan. 1st, 1924, no candidate who had not begun to study for D.P.H. before that date could present himself for qualification under the old curriculum. The new rules regarding the examination had been rather hardly spoken of by many people. He personally thought that the study entailed under the new curriculum could not possibly be got through in less than 12 months. In the past a medical officer of health had frequently come into conflict with a medical practitioner, and he thought that it was most necessary that a medical officer should himself, before he took up that office, have been in practice, as this would enable him to sympathise with the medical practitioner, who sometimes might make a wrong diagnosis in the case of some acute infection. In some ways Sir John Moore was opposed to the new regulations. He regretted greatly that when these regulations were drawn up all consideration of public services—the Navy, the Army, and the Air Force—had been lost sight of. It was extremely difficult for men in any of these services to get leave for such time as was required for study under the new regulations. The strongest protest against the new regulations had been made by the Royal Colleges of England. The rules now in force also made it very difficult for doctors in the colonies to obtain the diploma.

Dr. THOMAS HENNESSY said that in Great Britain there was a dictator of public health services, but in Ireland there had never been such an official, and he thought this was a pity. In the Local Government Board the medical men had practically no power at all, and the laymen always counted for much more than did the medical men. He himself had often wondered what was the actual worth of the D.P.H. In Limerick recently there had been an election for a tuberculosis officer and there were three candidates, two of whom had the diploma. The position was given to the candidate who did not hold the diploma, and the other two were rejected.

Sir WILLIAM THOMPSON said that he thought the work of preventive medicine was becoming of more and more importance, and that in the future medical men would be able to accomplish more good by it than by any other means. The Act regarding the notification of tuberculosis was, in his opinion, not framed strongly enough. By this Act it was only necessary to notify two classes of tuberculosis: (1) surgical tuberculosis—cases in which there was a discharge and where the wound had to be dressed; (2) pulmonary tuberculosis in the last stage. He felt sure that every medical man would agree with him that, as regards the prevention of tuberculosis

notification only of cases such as these was useless. Regarding infant mortality, he based his figures on the registration of births. For a number of years the infant mortality had been going down, and it was only during the last ten years that any Acts of Parliament had been brought in dealing with this matter; most of these Acts were voluntary, and not compulsory.

Dr. T. P. C. KIRKPATRICK said that the founding of the examination for D.P.H. in connexion with the College of Physicians was largely due to the work of Dr. Grimshaw, who was a very ardent supporter of public health. In March, 1882, he proposed that a Diploma in Public Health should be established, and in February, 1883, at his instigation the College of Physicians granted the D.P.H. after an examination.

Dr. J. C. O'FARRELL said he thought if the Section of State Medicine of the Royal Academy of Medicine in Ireland asserted itself more and brought itself into contact with the health authorities in Dublin that a great deal of good could be done regarding the health of the community. At present, for instance, houses were being built in which the rooms were absurdly small. These houses would accommodate large families and probably there would be six children sleeping in each room. Again, the supply of milk was unsatisfactory. Members of the Section of State Medicine of the Royal Academy of Medicine should make efforts to ensure that houses which were built had proper accommodation, that the rooms were sufficiently large, and also that a proper supply of good milk was obtained for the poor of Dublin. He believed that if the views of the section on these subjects were brought before the general public some good would result. He thought that to men in that country at any rate the D.P.H. was of very little use. Institutions for tuberculosis were governed and practically run by laymen, and the doctor, even if he had his D.P.H., was repulsed if he made any suggestions; he generally had no one to rely upon to back him up or to go to for advice. He thought if the health of the nation was to be improved the Section of State Medicine would have to assert themselves a great deal more and that the work which they did should be brought before the public and before the other authorities on public health.

ABERDEEN MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this Society was held on Jan. 17th, Dr. G. M. DUNCAN, the President, being in the chair.

Mr. F. K. SMITH read a paper on

Gall-stones: a Review of 120 Surgical Cases.

Mr. Smith, assisted by Mr. Gordon Bruce, had studied the records of 120 cases operated upon for gall-stones in the wards with which he had been associated, and from the information obtained he was able to draw certain conclusions with regard to the results of recognised methods of surgical treatment, the dangers associated with operation, the main causes of mortality, and the frequence of recurrence of biliary trouble. In many of the cases, 19 of which were males and 101 females, symptoms had been present for 10 or 15 years, with the result that there was an impaired biliary and hepatic system with the usual signs, in addition, of old-standing systemic disease, so that the operative risk was very high. The cases were divided into two classes—acute (i.e., the acutely infected cases, not necessarily those with acute biliary colic) and chronic.

The majority of the acute cases, after having premonitory signs of biliary disease for years, became rapidly ill with the suddenness typical of the acute abdomen. Mr. Smith traced the usual course of events in such cases, and referred to cases of special interest in his series, such as acute hæmatogenous cholecystitis and progressive cholangitis. Most of the acute cases were treated by cholecystectomy, and out of a total of 32 operated upon the mortality was 11, being much greater among men than among women. Of those who survived, 18 replied to a letter of inquiry sent out more than two years after operation, and 15 expressed themselves as in very good health. From his review of the acute cases, Mr. Smith concluded that improved results could best be obtained not by devising new operative measures, but by improvement in technique, and by reducing the number of acute cases—i.e., by earlier diagnosis or by earlier operation. Mr. Smith then detailed symptoms and signs which might be produced by an acute infection of the gall-bladder, and briefly discussed the comparative merits of cholecystectomy and cholecystostomy in these cases, some points in the operative technique, the prevention of hæmorrhage in jaundiced cases, and post-operative care in general. In the whole series there were five cases of malignant disease.

In the group of chronic cases there were ten of chronic cholecystitis without calculi, and in these multiple abdominal lesions were the rule. Most of these were treated by cholecystectomy but the results were poor. Cases of calculi in the common duct numbered 23; jaundice was present in about half the number. Of chronic cholelithiasis there were 55; 27 were treated by cholecystectomy with two deaths, the end-results in the survivors being good, and 28 by cholecystostomy, also with two deaths. From a general survey of this group Mr. Smith concluded that in these cases cholecystectomy gave better results than cholecystostomy as regards both general condition and recurrence of gall-stone symptoms.

Discussion.

Dr. J. CRUICKSHANK mentioned various theories of the causation of gall-stones which he tabulated as (*a*) infection; (*b*) hypercholesterolæmia; (*c*) possibility of some disorder of metabolism—suggested by the association of usual age, sex, and general obese type of patient. He described some animal experiments now being undertaken by which ordinary small stones (gravel) were implanted into the gall-bladders of rabbits, but what this might produce was not yet definitely established.—Mentioning the greater frequency of occurrence of gall-stone cases, Prof. JOHN MARNOCH gave this only as an impression, though a very definite one, formed during his own career as a surgeon in the north-east of Scotland. He stated that during the past 20 years or so gall-bladder calculi cases had undoubtedly become much more common in proportion as cases of vesical calculi had declined in number. Had change of diet, he asked, anything to do with it?—This impression was corroborated by Dr. J. E. SKINNER, of Skene, from his experience in general practice. He also laid stress on the importance of early diagnosis and early investigation of suspected cases from the point of view of the possibility of metabolic disorder.—Dr. A. G. ANDERSON, Mr. G. H. COLT, Dr. J. D. WHITE (who discussed the X ray investigation required), Dr. ROSS MACKENZIE (who recommended gas and oxygen as the anæsthetic of choice for operation), and Mr. G. S. DAVIDSON also spoke.

DEVON AND EXETER MEDICO-CHIRURGICAL SOCIETY.—The annual meeting was held at the Royal Devon and Exeter Hospital on Jan. 24th, the retiring President, Dr. G. P. Hawker, being in the chair for the business portion of the meeting. The Council of the society, in presenting their annual report, mourned the loss of three original members, two of whom had died during 1923—Drs. G. T. Clapp and J. Delpratt Harris, and Mr. A. C. Roper. The following were elected as office-bearers for 1924: President, Dr. C. Vincent Smith; vice-president, Dr. E. J. Toye; hon. sec., Mr. R. Wayland Smith; reporting hon. sec., Dr. G. L. Thornton; hon. treasurer, Mr. A. L. Candler; hon. auditors, Drs. Bernard Kelly and Shirley Steele-Perkins; Council, Dr. R. V. Solly, Dr. Ransom Pickard, Dr. R. Eager, Mr. N. Lock, Dr. A. Hipwell, and Dr. Dobson Smythe. Drs. R. V. Solly and Ransom Pickard were elected hon. members as an appreciation of the long and valued services they had given to the society. Cases were then shown.

Reviews and Notices of Books.

OBSTETRICS AND GYNÆCOLOGY.

A Combined Text-book, by J. M. MUNRO KERR, M.D., F.R.F.P.S. Glasg., Professor of Obstetrics and Gynæcology, Glasgow University; JAMES HAIG FERGUSON, M.D., F.R.C.S. Edin., Gynæcologist, Royal Infirmary, Edinburgh; JAMES YOUNG, D.S.O., M.D., F.R.C.S. Edin., Assistant Physician, Royal Maternity Hospital, Edinburgh; and JAMES HENDRY, M.A., B.Sc., M.B., Senior Assistant to the Muirhead Professor, University of Glasgow. Edinburgh: E. and S. Livingstone. 1923. Pp. 1006. 35*s*.

THE first attempt to close the gap which exists between the art of midwifery and that of the treatment of diseases peculiar to women was made in the "Encyclopædia of Midwifery and Diseases of Women," edited by Dr. John S. Fairbairn in 1921, a monumental work of reference well adapted to the needs of the practitioner. In the present volume the same principle is adopted in the compilation of a text-book, which, as the authors note in the preface, is intended to impress the medical student with the fact that the great majority of ailments encountered in gynæcological practice are the result of infections and injuries contracted during parturition. With this statement few will disagree, but in a composite volume there may be some divergence of opinion as to the relative amount of space that should be devoted to each subject. In the present instance, the authors have given roughly three-fifths of the book to obstetrics and two-fifths to gynæcology. The volume is divided into ten parts. The first of these deals with anatomy and physiology and methods of examination, both in the non-pregnant and pregnant state. The next seven sections are devoted exclusively to the discussion of obstetric subjects. Gynæcology is relegated to the concluding two sections of the book, the first comprising chapters upon diseases of the female pelvic organs, including the bladder, rectum, and pelvic colon, and the last section including surgical technique and a description of various gynæcological operations.

However simple the principle may seem, the task of correlating two subjects, even so closely related as obstetrics and gynæcology, is no easy one, but this volume may be taken as a notable and praiseworthy attempt to deal with a difficult problem. Part I. attains the authors' object admirably, and we should like to see the same fusion in other sections of the book. The arbitrary wall between the two sciences still appears a little too high, and might be further broken down with advantage. For example, is it too much to hope that some day we shall see "displacements of the uterus and pelvic floor" considered primarily as a late obstetric complication? The same applies to certain chronic inflammatory conditions of the pelvic viscera still retained in the purely gynæcological chapters of the book. The connecting chapter between obstetrics and gynæcology might be developed in subsequent editions with considerable advantage, or, better still, a new "Part" introduced to include in a series of chapters all those diseases which are the result directly and indirectly of the pregnant state. The gynæcological sections would undoubtedly suffer, but the avowed aim of the authors to correlate more closely obstetrics and gynæcology would, we think, be still further attained. The subject-matter of the book is excellent, and there is an absence of debatable material which is commendable in a book designed for the student. The chapters dealing with obstetrics are particularly good, and the value of the text throughout is increased by the inclusion of a series of figures admirably reproduced, many of which have already done good service in Kerr's "Operative Midwifery and Clinical and Operative Gynæcology."

The book is a notable advance in teaching, and both student and practitioner will undoubtedly appreciate the advantage of possessing in one cover a symposium of modern views covering all that is necessary in the allied sciences.

ENDOCRINE DISEASES.

Including their Diagnosis and Treatment. By WILHELM FALTA, Professor of Medicine, Vienna. Translated and edited by MILTON K. MEYERS, M.D., Neurologist to the Northern Liberties Hospital, Philadelphia. London: J. and A. Churchill. 1923. With 104 illustrations. Pp. 669. 36*s*.

Dr. Meyers has brought out a third edition in English of Prof. Falta's well-known book on ductless glandular diseases. The title has, however, been altered to that of Endocrine Diseases since this name has now come into general use. In the ten years which have elapsed since Falta published the original work a great deal of new and important work has been done. The editor has endeavoured to add this to the latest edition and it is a great advantage to have this new work incorporated, especially since in each section it is so arranged that it can be read separately, while the original text can be followed easily. Where a statement of Falta's has been completely disproved the correction is made. The introductory chapter gives a general survey of the action of the ductless glands which is of great interest and has been brought up to date by the editor. In the next two chapters 120 pages are given up to the discussion of the thyroid gland and its diseases and make interesting reading. The newer work does not essentially alter Falta's views, though thyroxin, the active principle of the gland, has been isolated and prepared. Falta's objections to dysfunctions are supported by the editor, although he does not think that the question is finally settled. No mention is made of the observation that auricular fibrillation often occurs in severe cases. The diseases of the pituitary are very fully dealt with, although the reproductions of the skiagrams are not clear. The chapter on the pancreas is the least satisfactory, since so much new work had been done on the physiology of the Islands of Langerhans even before the discovery of insulin. Falta's account is now inadequate and the editor has not added much of the new work, although there is a bare reference to insulin. The parathyroids and suprarenals are well described.

The translation has, on the whole, been well done, although the construction of the sentences is often on German lines, and some of the translations are clumsy. The references to the literature are placed at the end of the book instead of after each chapter, but are extensive and useful. There is a good chapter index and also a full index. The book is a valuable one if only because of the amount of information which is collected together. It is well printed and bound.

UROLOGY.

By E. L. KEYES, M.D., Ph.D., Professor of Urology, Cornell University Medical College; Urologist to Vincent and to Bellevue Hospitals. London: D. Appleton and Co. 1923. Pp. 781. 35*s*.

THIS is the fourth revision of a well-known text-book. There are a number of changes. New methods have been introduced, two new sections, on suppurative inguinal adenitis and granuloma inguinale, added, whilst gonorrhœa in the female and syphilis have been dropped as having no place in urology. The book is so widely known that detailed criticism of this edition is not necessary. The author has brought the work thoroughly up to date and his recommendations throughout bear the stamp of practical experience. The prominence given to the phenol-sulphonephthalein test of renal function labels the country of

origin of the book. It seems curious to our workers that the American surgeon almost never employs such a simple and efficient test as that of the urea-concentrating power of the kidney. But there are subjects dealt with in this book, such as perineal prostatectomy and operations upon the seminal vesicles, which are inadequately treated in our own text-books. It seems a little pessimistic to speak of implantation of the ureters into the rectum for exstrophy of the bladder as a "confession of failure," but the teaching throughout is sound in a large volume on an extensive subject. The book is well illustrated and should certainly maintain its popularity.

An Introduction to Surgical Urology. By W. K. IRWIN, M.D., F.R.C.S. Edin., Honorary Casualty Out-patient Surgeon, St. Paul's Hospital for Genito-Urinary Diseases. London: Baillière, Tindall and Cox. 1923. Pp. 180. 7*s.* 6*d.*

THIS small book has been written that it may help to elucidate the outstanding features of surgical urology, a subject which the author describes as a "terra incognita to many practitioners" without justifying his criticism of his colleagues. After preliminary sections on anatomy and clinical examination, separate chapters are devoted to the several symptoms of urinary disease, such as frequent micturition and pyuria. Whilst this arrangement has certain advantages, it renders it difficult to collect the scattered information about any particular urinary condition. In the case of prostatic disease there appears a systematic chapter dealing with this derangement alone. The teaching soundly reflects the practice of English urologists. There are no illustrations.

ATLAS OF OTOLOGY.

Illustrating the Normal and Pathological Anatomy of the Temporal Bone. By ALBERT GRAY, M.D., F.R.S.E., F.R.F.P.S.G., Lecturer on Diseases of the Ear, Glasgow University. Glasgow: MacLehose, Jackson and Co. 1924. Pp. 49. £6 6*s.*

WE congratulate Dr. Gray on the production of a beautiful atlas. The plates are exquisite reproductions of the author's own photographs of specimens prepared by himself, and they must represent many hours devoted to this labour of love. A large number of the photographs are stereoscopic, a method particularly valuable in bringing out minute details of the anatomy of the temporal bone; a small stereoscope consisting of a pair of convex lenses is provided with the book. Most of the pictures are in magnification, the degree being always stated in the text, and several are photomicrographs. The atlas consists of 44 illustrations of normal and 19 of pathological anatomy, the principal subjects shown being the changes due to suppurative otitis and to otosclerosis; for his researches into the pathology of the latter disease Dr. Gray has obtained a very high reputation, which gives an additional interest to his specimens. Each illustration is accompanied by a short explanatory text. Dr. Gray states that he is aware that this work does not give a complete presentation of the subject, and hints that a supplementary volume may be published at a later date. To this event otologists will look forward with eagerness.

CURES.

By JAMES J. WALSH, M.D., Ph.D., Sc.D., Professor of Physiological Psychology, Cathedral College and College of the Sacred Heart (Manhattanville), New York. London and New York: D. Appleton and Co. 1923. Pp. 284. 8*s.* 6*d.*

Prof. Walsh has written an entertaining book on "cures which have failed"—that is, cures which have been in fashion for a season as panaceas for all mortal ills and then have died a natural death, just as their supporters did. The subject is dealt with in a tolerant, often humorous, vein. "Poor human nature," says the author, "when ailing, like a drowning man, grasps at a straw, only the amusing thing is that his mind so often turns the straw into a solid beam of hope on which he floats into the harbour of good health when he thought he was seriously ill. Why should not human nature have its delusions when they add to the happiness of men? It is not with the idea of eradicating the delusions that this book is written, but so that we may altogether laugh a little quietly at this human nature of ours and its humorous ways." Somewhat prophetically, perhaps, neither psycho-analysis nor Mr. Coué are spared. In showing that most of the "cures" were effected on the malade imaginaire, the book itself will doubtless prove a most effective cure—for a season—for that type of patient who is for ever seeking something new, and to such the physician might well prescribe it.

CLEFT LIP AND PALATE.

By T. W. BROPHY, D.D.S., M.D., LL.D., F.A.C.S., O.I., Sc.D., F.A.C.D., Emeritus Professor of Oral Surgery, Chicago College of Dental Surgery; formerly Professor of Dental Pathology and Surgery, Rush Medical College. London: Henry Kimpton. 1924. Pp. 340. 30*s.*

IN this book the author describes his views on a controversial subject, the treatment of cleft palate. It embodies the experience of 40 years and the author has operated upon a very large number of patients. Since 1915 he has performed nearly 2000 cleft palate operations and the total number to his credit is 5076. The teaching derived from such a vast experience demands our most careful attention. Though the author described a bone operation many years ago, the principles upon which it was based have not been fully appreciated in this country, where it has never been given an extended trial, and has been condemned by some surgeons perhaps too hurriedly. There is a mass of evidence retailed in this volume which speaks for the soundness of the author's methods and calls for a practical investigation of its truth. Although an enthusiast for his own operations, the author does not push his recommendations beyond the limits of prudence, and when need be employs the methods worked out by other authorities. It would require a good deal of evidence to refute two of his principles—that early closure of the cleft gives a greater likelihood of perfect speech and that tension-relieving muscular incisions in the soft palate always tend to be destructive of speech prospects. To grasp the fundamental ideas underlying the author's treatment, the book must be read. Suffice it to say here only this, that the criticism so often made that the early bone operation on infants is a dangerous one, is not supported by the statistics set forth in the book; the percentage of deaths in children operated upon during the first year of life has amounted since 1915 only to 2·9. This is little more than one-third Chicago's infant mortality for the same age, but it must be remembered that the children are required to reach a certain standard of health before operation can be contemplated.

The book should certainly be consulted by all those who treat this deformity in children.

JOURNALS.

JOURNAL OF PATHOLOGY AND BACTERIOLOGY. Vol. XXVII., No. 1. Pp. 1–144. January, 1924.—A Stable Preparation of Hydatids for the Complement-fixation Test, by S. W. Patterson and Miss F. E. Williams (Melbourne). An alcoholic extract of scolices from the cysts in infected men or animals, evaporated to dryness and taken up in salt solution forms a stable specific preparation for the diagnosis of hydatid disease. It should be particularly useful in places, such as England, where such diagnostic tests are wanted only occasionally.—The Significance of Anisotropic Fatty Substances in Myelomatous Tumours, by S. C. Dyke (London). A myeloma

of the head of the tibia and two tendon-sheath myelomata all show foamy cells stuffed with doubly-refractile cholesterol-esters. This is in favour of the endothelial origin of these tumours.—The Histology of the Central Nervous System in an Acute Case of Encephalitis, by C. Da Fano (London). A case of lethargic encephalitis fatal in 36 hours. The author gives a beautifully illustrated account of the histological changes and of the occurrence of the "minute bodies" previously described by him.—The Effects of Vitamin-Deficient Diets on Rats with special reference to the Motor Functions of the Intestinal Tract, by L. Gross (London).—The Morbid Anatomy, Histology, and Blood Changes in Anaphylaxis in the Dog, by H. R. Dean and R. A. Webb (Manchester and Cambridge).—The Effect of Experimental Exclusion of the Liver on the Formation of Bile-pigment, by J. W. McNee and B. Prusík (London). In 15 experiments hæmoglobin was introduced into the circulation of dogs from which the liver was completely excluded; in two cases only was the formation of any bile-pigment determined. The conversion of hæmoglobin to bilirubin does not therefore take place rapidly in the absence of the liver.—The Quantitative Estimation of Isohæmagglutination, by C. Price-Jones (London). No quantitative studies of the group agglutinations of human red cells seem to have been published. The degree of agglutination varies directly with time and the concentration of serum, and also with the concentration of red cells, thick suspensions showing relatively more agglutination than thin ones. The author was unable to separate mixtures of red cells of different groups quantitatively with a serum which should agglutinate one group only. With dilute suspensions, care must be taken to avoid contact hæmolysis.—An Aldehyde Mordant for Fats and Lipoids, by J. Lorrain Smith and T. Rettie (Edinburgh). Acetaldehyde is a good mordant in the bichromate-hæmatoxylin method of staining lipoids.—Celluloid Museum Jars, by W. D. O'Kelly (Dublin). Directions for making serviceable jars from thin sheet celluloid.—Staining Tubercle Bacilli in Formalin-fixed Tissues, by E. G. D. Murray (Cambridge). Tubercle bacilli are difficult to stain after formalin fixation; this may be corrected by the destruction of the formalin by ammonia.—The Application of a Sulphite-glucose-iron Agar Medium to the Quantitative Estimation of *B. welchii* and other reducing Bacteria in Water-supplies, by W. J. Wilson and Miss E. M. Blair (Belfast). A useful addition to the bacteriological tests of water.—The Antiseptic Action of Anil-pyridines and Anil-quinolines, by C. H. Browning, J. B. Cohen, S. Ellingworth, and R. Gulbransen (Leeds and Glasgow). A continuation of the authors' important studies on the relation between chemical constitution and bactericidal action.—Cystine in Bacterial Metabolism, by J. Gordon (Leeds). Organisms such as the coli-typhoid group and the anaerobes which can break up cystine with the formation of H_2S grow well in cystine media; more delicate organisms which cannot split it are highly sensitive to small concentrations. Serum has some protective effect.—A Malignant Tumour of Kidney, by J. B. Duguid (Aberdeen).—The Preparation of Dry Bone Specimens, by W. E. M. Wardill (Newcastle).—Digestion with Cultures of staphylococcus, *B. proteus*, and *B. sporogenes* gives good results.—The Histology of the Gall-bladders Excised from Three Enteric Carriers, by R. P. Smith (Glasgow). A subacute cholecystitis affecting mainly the interstitial tissues was found in each case, in one instance with a markedly focal arrangement.—The Germination Period and Mortality of Anthrax Spores, by M. B. R. Swann (Cambridge). The time taken till the first division of the bacillus is with young spores uniformly about 70 minutes at 37°C; with old spores it varies from two to seven hours. About 5 per cent. of young and about 55 per cent. of old spores are dead.—The Influence of the Visible Spectrum on the Growth of Bacteria in Artificial Culture, by T. J. Mackie and S. van der Lingen (Cape Town). The varying reactions of the different organisms tested cannot be summarised; on the whole, red light had the greatest inhibitory effect, but as the intensity of illumination was controlled by an actinometer it is not clear that the results are comparable. In some cases the inhibitory effect of the whole spectrum was less than that of a fraction.—A Pipette Controller for Measuring Small Quantities of Fluids, by E. C. Smith (Dublin).—Diphtheria: Problems in Schick Testing and Active Immunisation, by R. A. O'Brien (London). Five statements may now be made which are so nearly true that exceptions are of no practical importance: (1) Schick negatives are not susceptible to diphtheria; (2) Schick positives are susceptible; (3) Schick positives never harbour virulent bacilli unless they have diphtheria; (4) carriers of virulent bacilli are always Schick negative; (5) avirulent bacilli do not cause diphtheria.—Sacrococcygeal Teratoma containing Gliomatous, Chordomatous, and Ependymal-carcinomatous Tissue, by K. G. Pandalai, W. L. Forsyth, and M. J. Stewart (Leeds).

ARCHIVES OF INTERNAL MEDICINE. Dec. 15th, 1923.—Thyroid Physiology in the Control of Thyroid Disease, by David Marine, New York. Thyroid physiology is reviewed with particular reference to the effect of relative or absolute iodine deficiency on the structure of the gland. The influence of the interrenal glands on thyroid activity is dealt with and the results of adrenal insufficiency experimentally produced in rabbits are recorded. The subject is discussed in relation to the ætiology of exophthalmic goitre.—Elective Localisation in the Eye of Bacteria from Infected Teeth, by Russell Haden, Kansas City. Cultures grown from the root tip or pulp of patients suffering from metastatic eye infections were injected into 66 rabbits; 45 of these developed eye lesions. Similar cultures from the teeth of patients not suffering from eye infections were injected into 169 rabbits, and of these only 25 developed eye lesions. Case histories and good illustrations are given.—Renal Injury Produced in Rabbits by Diets Containing Meat, by L. H. Newburgh and S. Clarkson, Ann Arbour. Rabbits were fed for varying periods on a high protein diet. The majority of rabbits that ate a diet containing 27 per cent. or more of protein for six or more months developed a chronic nephropathy.—Periarteritis Acuta Nodosa, by W. Ophuls, San Francisco. Very complete clinical and pathological details of a case of periarteritis nodosa are recorded, together with micro-photographs of the lesions and extensive bibliography. The author suggests that the disease has some relation to subacute "septic rheumatic" infections.—E. B. McKinley, Dallas, reports the treatment of seven patients suffering from various infections with the bacteriophage of Twort and d'Herelle.—C. P. Miller and A. Branch, New York, report the clinical course and post-mortem findings in a case of subacute bacterial endocarditis due to a hæmolytic hæmophilic bacillus.—I. M. Rabinowitch, Montreal, maintains, on the basis of observations made on 200 patients, that the urea-concentration factor is a more sensitive test of renal efficiency than the other tests now in use.—Treatment by Splenectomy of Essential Thrombocytopenia, by N. E. Brill and N. Rosenthal, New York. The cardinal signs of essential thrombocytopenia (purpura hæmorrhagica) and the reasons for regarding it as a distinct clinical entity are given. Two cases of the disease are reported in detail, in both of which striking improvement followed splenectomy. The pathogeny of the condition is discussed and there is a bibliography.—Douglas Vanderhof reports seven cases of Subacute Combined Degeneration of the Cord with absence of free hydrochloric acid in the stomach as determined by fractional test-meal analysis. Emphasis is placed on the importance of adequate hydrochloric acid therapy in this condition.

Messrs. W. Heffer announce that two books by Dr. T. S. P. Strangeways, on "Tissue Culture in Relation to Growth and Differentiation," and on "The Technique of Tissue Culture in Vitro," will shortly be published.

The Conduct of Medical Practice.

A Series of Articles by Experts dealing with the Difficulties Encountered in Professional Life and How to Meet Them.

V.—TRANSFER OF PRACTICES: POINTS FOR THE VENDOR.

BY COLIN M. OLIVER
AND
OSWALD A. HEMPSON.

It is naught, it is naught, saith the buyer; but when he is gone his way, then he boasteth.
—Proverbs xx. 14.

IN a previous article we dealt with certain points which, it was hoped, might be useful to a medical man when seeking to purchase a practice. In this article we propose to consider a few matters which may be of interest and assistance to those members of the profession who contemplate selling the whole of, or a share in, an established medical practice.

Employment of an Agent.

Having decided to sell his practice, the first step is obviously to get in touch with likely purchasers, and to place before them as clearly and concisely as possible full details of the practice. To this end a vendor should consider first whether he desires to employ the services of an agent or to get in touch with prospective purchasers direct through the medium of an advertisement in the medical press. If the former course is decided upon, he should be careful to select a reputable medical transfer agent upon whom he can rely to safeguard his interests.

In employing an agent the vendor should realise that the agent's commission is payable by him as vendor, and before giving definite instructions for the disposal of the practice he should ascertain the scale of such commission, and on what it is actually based and to what it extends. Further, in order that there should be no possibility of dispute at a later date, he should take care to agree when such fee shall be deemed to be earned by the agent and payable to him. For example, whether when the contract is signed, when a willing purchaser is introduced, or when the purchase money is actually paid.

It is inadvisable to instruct more than one agent as if, as sometimes happens, particulars of the practice are sent to a purchaser by more than one agent they may both claim commission as being the agent instrumental in effecting the sale. Some of the better-class agents have a mutual arrangement by which in such circumstances the commission is divided between them, or else an agreement between them provides for the ready determination of the question. Unfortunately, all agents are not parties to such an arrangement, and in case of dual claims difficult questions will arise as to which agent actually introduced the purchaser, and in the end the vendor may have to pay two or more commissions. This danger can be met by arranging with the agents when instructing them that, if any such question does arise, only one commission shall be payable, which must be shared amongst them.

If the vendor prefers to dispense with the services of agents, he can do so by inserting his own advertisement in the medical press. In this event, he should take care not to give full indication of his identity or the exact locality of his practice, as it is in some cases very damaging to the practice if the patients hear that there is likely to be a change before the purchaser is actually introduced into it. In addition there is the danger of a not too scrupulous agent taking advantage of the knowledge thus gained to introduce a purchaser and thus try to establish a claim for commission.

Supply of Information.

Having placed the disposal of the practice in train, the vendor must be prepared to supply all reasonable information which a purchaser may require. At this point it is permissible to emphasise the importance of keeping clear and accurate accounts of a practice in such a form that an accountant or other investigator of the accounts on behalf of a purchaser can easily follow them so as to check the gross income for the purpose of verifying the purchase price, and to ascertain the various sources from which the income is derived.

The purchase price is usually based upon an agreed number of years' purchase of the average gross receipts for the three years immediately preceding the date of purchase. In order to enable the investigator to verify the earnings of the practice, it is most advisable to pay all takings from the practice into a banking account, whether such takings are received in the form of cheques, postal orders, or cash, as by so doing the bank pass-book acts as a check upon the figures shown in the books of account.

In a previous article we enumerated the scope of the inquiries which a careful purchaser should make when investigating a practice offered to him for sale. It is not therefore proposed to set these out again. A vendor should be prepared with all the information there suggested. He should obviously take care to state fully all the advantages of the practice, but it is of equal importance that he should not conceal or withhold information which might affect a purchaser in deciding to buy. It is true that the legal maxim "caveat emptor" applies to these transactions, but this would not be an adequate defence to an action for damages by a disappointed purchaser where there has not been a full disclosure of material facts or where there has been misrepresentation of facts. For his own protection, too, the vendor must bear in mind that whatever he may do he cannot guarantee that his successor will retain the practice which he has bought, so he should ensure that, even though disappointed, the purchaser can have no claim upon him for his lack of success.[1]

Payment by Instalment.

In the previous article also we discussed the amount of the purchase price, but it should be remembered that the prices there referred to relate to an average practice possessing no specially attractive features. Where such features exist, a vendor may ask and expect to receive an increase upon such average purchase price commensurate with the special features. He should remember that the amount to be realised is ruled by the question of supply and demand when dealing with medical practices as much as in dealing with commercial commodities.

Having found a purchaser, and having satisfied his inquiries, it is often found that such purchaser is unable to pay the whole of the purchase money in cash, and accordingly may ask to be allowed to pay for the practice by instalments. At the present time when capital is scarce, a vendor will often be well advised to accept payment in this manner, provided that a substantial amount is paid down in cash and adequate security is given for payment of the balance, and also that interest is paid upon the balance from time to time outstanding. It is, of course, essential to examine the security offered somewhat critically, as once a purchaser has entered into possession of the practice it will certainly be difficult and often disastrous for a vendor to return to it if the purchaser makes default in payment.

Security for Deferred Payment.—The security may take a variety of forms. The most usual are a guarantee by some third person, a deposit of actual securities, or, in the case of a panel practice, a charge on the panel receipts. When a guarantee is offered, the vendor should obviously make careful inquiries as to the financial standing and position of the guarantor. The guarantee can be effected either by joining the guarantor as a party to the assignment of the practice

[1] It should also be borne in mind that litigation even for the successful litigant is an expensive matter, and so the vendor should be careful to lay before the purchaser everything which is material.

from the vendor to the purchaser or by separate instrument.

It is unnecessary to comment upon the second alternative, except to point out that when a life assurance policy is offered as security, its surrender value should be ascertained and it should only be regarded as an actual security to the amount of the surrender value. A new policy which has acquired no surrender value is therefore of no actual security, except in the case of the death of the purchaser before the whole of the purchase money is paid. From this aspect a life policy is a good security, but it should be considered as a collateral only and not a primary security.

The charge upon the panel receipts—which is perhaps one of the most satisfactory forms of security—is effected by the purchaser agreeing with the vendor that the cheques payable by the insurance committee in respect of the panel patients of the practice shall be paid to the vendor until the balance of the purchase money and interest thereon is paid. It is, however, sometimes provided that such cheques shall be paid to and received by the purchaser until he shall make default in payment of any instalment or interest, in which event the vendor shall be at liberty to give notice to the insurance committee requiring the cheques to be paid to him until all sums payable have been received.

Where the purchase money is payable by instalments the vendor should insist that, in the event of the purchaser selling the whole or any share of the practice before he has paid for it in full, the balance of the purchase money then owing shall forthwith become payable, and a clause to that effect should be inserted in the assignment of the practice to the purchaser.

Book Debts.—If these are sold with the practice they must be valued in order that the purchase price may be ascertained and due allowance must be made for bad and doubtful debts. In this case, the purchaser should be given a power of attorney to enable him to collect them, such power of attorney is incorporated in the assignment of the practice. By adopting this course a vendor will relieve himself of the trouble and expense of collection.

If the book debts are not sold with the practice, it is fair that the vendor should submit to a clause in the assignment whereby he is precluded from taking proceedings to recover the amount due from any patient for a period of 6 to 12 calendar months from the date of the sale of the practice, except where a patient dies, becomes or is likely to become bankrupt, or leaves the neighbourhood, and except where the debt is likely to become irrecoverable by the operation of the Statute of Limitations unless proceedings are taken for its recovery at an early date. In this event, also, it is not unreasonable to allow the purchaser a commission not exceeding 10 per cent. upon any book debts which he may collect for the vendor.

Restraining Clauses.

A vendor must also submit to a clause in the assignment precluding him from practising within a reasonable radius from the centre of the practice. A purchaser, however, cannot ask that this radius shall be wider than is necessary for the purpose of affording him adequate protection from competition by the vendor. If it is arranged that the purchaser should have a preliminary partnership, or should serve as an assistant to the vendor before exercising his option to purchase, the vendor should insist that the agreement should also contain a clause precluding the purchaser from practising in opposition in the event of the purchase not being completed.

If the vendor is selling his practice with a view to giving up general practice and devoting himself to practise as a specialist or consultant, the clause restraining him from practice should be so worded as to permit of his so doing, but in such circumstances it would not be unreasonable for the purchaser to ask for some rebate in the purchase money by reason of the fact that the vendor is allowed to attend patients of the practice even as a specialist or consultant. The vendor also might expect the purchaser to insist on the deduction from the gross receipts on which the purchase is to be based of any fees derived from consultations or from the special branch of medicine or surgery to which the vendor intends thereafter exclusively to devote himself.

The definition of the term consultant or specialist is by no means easy, but for his own protection, and in order to avoid dispute in the future, it is very desirable that these terms should be defined as closely as possible in the assignment. It will usually be of sufficient protection to the purchaser if in such cases the vendor is bound to charge a minimum fee of from 2 to 3 guineas for every consultation upon any person who has been a patient of the practice.

The vendor must also remember that the restraining clause operates not merely for the life of the purchaser, or the period of his retention of the practice, but unless restricted in point of time by the actual terms of the assignment, it attaches to the goodwill, and the benefit of it can be assigned to the successor of the purchaser, and so on, throughout the life of the vendor.

In this article we have dealt almost exclusively with the sale of an entire practice, but most of our remarks, warnings, and comments apply equally to the sale of a share in as to the sale of an entire practice. In the sale of a share of a practice, the actual assignment is embodied in the articles of partnership which set out the rights and obligations of the parties.

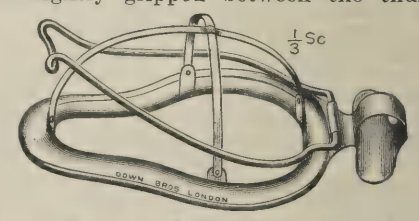
A Warning.

One last word. Every medical man, before selling his practice or a share in it, should make certain that the purchaser is a duly registered medical practitioner. This may sound obvious, but experience has shown that this is necessary, as even that excellent publication, the Medical Directory, has been misled before now, and contained the names of persons who have fraudulently assumed the name and qualifications of a deceased practitioner, and the only sure and certain test is to consult the Medical Register and there identify the purchaser.

New Inventions.

A NEW ANÆSTHETIC MASK.

The usual pattern of the Schimmelbusch mask appears to me to have two defects: (1) The handle is made at the wrong end—i.e, the upper, or nasal, end—so that if the anæsthetist holds the handle of the mask in one hand and a drop bottle in the other he cannot control the patient's jaw at all readily. (2) The handle itself is a small piece of plain metal, which must be tightly gripped between the thumb and



one or more fingers to hold it in position, leaving the ring and little fingers, the least efficient fingers, to support the jaw. To overcome these defects I have had a mask made, shaped to the face, and fitted with a handle at the lower, or chin, end. Further, in place of the ordinary handle I have suggested a ring grip for the fingers, which allows control of the mask without constant apposition of thumb and fingers, permitting greater freedom and less fatigue. The grip may be single or double, but in most cases I think the single ring will suffice. Messrs. Down Bros. have made the mask for me, and have taken great care and trouble in carrying out my suggestions.

Geoffrey Dunderdale, M.D. Lond.
Pietermaritzburg, Natal.

THE LANCET.

LONDON: SATURDAY, FEBRUARY 2, 1924.

THE DECLINE IN TUBERCULOSIS.

TUBERCULOSIS is a department of medicine in which it is notoriously difficult to see the wood for the t.b.'s. The individual worker is all too ready to attribute the reduced mortality from the disease to individual methods in which he is personally interested, while the central observer who studies the epidemiological curve may become sceptical of the value of effort at all. To both of these Dr. A. S. MACNALTY'S comprehensive review of tuberculosis work in England, which appeared at the front of our last issue, may help to bring perspective. Dr. G. LISSANT COX spoke of the organisation of county schemes recently at the Royal Institute of Public Health (THE LANCET, Jan. 26th, p. 213). We leave these reviews to speak for themselves, and turn to the problem as it presents itself in America. In the year 1900, the first year for reliable statistics on tuberculosis for any large part of the United States, the death-rate from this disease was 195 per 100,000 of population. In 1910 it had become 165 for the same geographical area, a drop of 15·6 per cent., and in 1920 it had fallen to 112, or nearly 43 per cent. lower than in 1900. In the experience of some 15 million persons insured in the Industrial Department of the Metropolitan Life Insurance Company, between 1911 and 1921 the death-rate had declined over 49 per cent., a figure even more remarkable than that for the entire population. To the causes and auxiliary conditions which can be regarded as having helped in securing this result, Dr. LOUIS I. DUBLIN has devoted an interesting address, delivered before the American Tuberculosis Association and now reprinted, which has a useful bearing on English experience.

Two explanations are given of this change in the experience of America and of other countries, the first alleging that the change is due primarily to activities within human control, while the second minimises the importance of environmental factors in the control of tuberculosis, and emphasises the all-importance of the genetic—that is, the constitutional factors. Infection is admittedly necessary, but according to the geneticists, the fate of those infected depends on inherited qualities. If the latter view prevails it follows that current anti-tuberculosis activities are relatively unimportant, and that in this matter "natural selection may have done more for racial health than medical science." In analysing the facts bearing on these two views Dr. DUBLIN lumps together all environmental factors, leaving almost undiscussed the question as to the relative value of different measures—e.g., early treatment of the sick, segregation of advanced and bedridden patients, familial and industrial hygiene, improved nutrition, &c., and we may do the same, while expressing the hope that a later effort may be made to associate and evaluate different environmental factors with varying degrees of fall in the tuberculosis death-rate. Meanwhile the broad argument as to the relative value of environmental factors in toto and of genetic influences as developed in Dr. DUBLIN'S address deserves summarisation. How do the extreme variations in the geographical distribution of the death-rate from tuberculosis concord with the genetic view? It is not likely that the people living in Akron (death-rate 47) are inherently more healthy than those in New Haven, Conn. (death-rate 81). So likewise the difference between urban and rural death-rates and between various rural districts cannot be entirely explained on such a hypothesis. A similar remark applies to the local variations in tuberculosis mortality according to age and sex. If genetic influences are preponderant, how does it arise that in the experience of the Metropolitan Company the male death-rate among whites now reaches its maximum at the age of about 42 and is then 477, while the female maximum is at the age of 27 and is 240 per 100,000? The changing relationship of the death-rate in the two sexes with advancing age is difficult to explain except as the result of changing environment.

The racial incidence of tuberculosis is compatible with the view that in the development of this disease an inherited racial immunity plays a part. The experience of exceptionally low mortality from tuberculosis among Russians and Jews and Italians in the United States is regarded by Dr. DUBLIN as supporting the above-stated view, and even more striking evidence as to racial differences has been adduced by Dr. G. E. BUSHNELL and Prof. LYLE CUMMINS. Whether these differences are evidence of the working of natural selection or arise from varying degree of exposure to infection in early life, or whether in the case of the Russian, Jew, and Italian experience they may be attributed partially to the greater amount of fatty food (e.g., olive oil) in their dietaries or to all these factors, cannot be completely decided in the absence of more complete evidence. But even if, as is possible, race bears a part in the result, environment plays its part to colour the racial picture, and in all cases a higher or a lower death-rate is obtainable with various modes and stations of life. The well-known variations in the death-rate from tuberculosis in accordance with economic level, of which a striking example in insurance experience is given by Dr. DUBLIN, and, still more, occupational variations in mortality from tuberculosis, point to the predominant influence of environment. The strongest and most enterprising rural population migrate into towns; but in the English Registrar-General's statement of occupational mortality there are no less than 26 occupational classes which show a mortality from phthisis almost four times as great as farmers. To indoor industries must be attributed this difference in the main, when the special alcoholic industries are excluded, and in producing this result massive infection as well as reduced resistance of the operative plays a chief part. Perhaps the most enlightening portion of Dr. DUBLIN'S review is that showing recent changes in the tuberculosis death-rate. In his insurance experience a reduction approximating 50 per cent. has occurred in 11 years. The greatest decline has occurred where the rates were originally highest and least where the rates were lowest. In America the age-incidence of the disease has changed to a remarkable extent, showing that age-incidence is a fluid phenomenon "responding," to quote his words, "quickly and incisively to external modifications when these are properly chosen and well directed." Compare these changes with the increased tuberculosis death-rate in many European countries, and the picture is consistent far more with the first than with the second of the two explanations—with environmental rather than with genetic influences.

This explanation, furthermore, gives hope for the future and stimulus in the pursuit of all known measures of prevention. The lines of action which have

been most closely associated with the decline already secured have been dual in character. Massive and repeated infection, especially of the young and adolescent, have been rendered less common and their dosage decreased; and many influences, including educational, have combined to produce more cleanly habits of the people, reduction of dust, and other evils in industrial life, and generally improved nutrition of the population. The dissection of the relative value of these and other environmental factors is a task of great complexity for which the data possibly do not exist; and personal differences of opinion as to the importance of each factor meanwhile will persist. But this is of relatively small practical importance if the principle of attack on tuberculosis from every point of view be accepted. It is by combined attack on all lines, carried forward with confidence and perseverance, that we may anticipate ere long, in this country as in America, a general tuberculosis death-rate of 50 per 100,000. This figure has already been attained in New Zealand and in Australia, and Dr. DUBLIN anticipates the attainment of the same figure in the United States by the year 1930.

NATIONAL HEALTH INSURANCE.

THE Court of Inquiry into the remuneration of insurance practitioners, whose deliberations were summarised in our pages last week, reported just after we had gone to press. The award is as follows:—

> The amount of the capitation fee per insured person per annum on the basis of which the Central Practitioners Fund under Article 19 of the National Health Insurance (Medical Benefit) Regulations, 1924, should be calculated as from the 1st January, 1924, so as to afford adequate remuneration for the time and service to be given by general practitioners under the conditions set out in those Regulations in connexion with the medical attendance and treatment of insured persons, due regard being had to the service in fact rendered under the Regulations hitherto in force (such capitation fee not to include any payment in respect of the supply of drugs and appliances nor any payments to meet the special conditions of practice in rural and semi-rural areas), is nine shillings.
>
> In the course of the inquiry it was stated on behalf of the Minister of Health and the Secretary for Scotland, and on behalf of the British Medical Association that our finding was only intended to be binding for the year from the 1st January, 1924, to the 31st December, 1924, but that both parties desired the Court to make a recommendation covering such longer period as we should think fit.
>
> We therefore recommend that the capitation fee of nine shillings so found by us should remain in force for a period of three years from the 31st December, 1924.

Thus the capitation fee regarded by the Court as adequate remuneration for the practitioner's time and service exceeds by 6*d*., or nearly 6 per cent., that offered by the late Minister of Health, and its award fully justifies the appeal by the insurance medical service to an independent tribunal. The Court recommends that the capitation fee now awarded should remain in force until Dec. 31st, 1927, a period which will ensure the tranquillity so desirable for the smooth working of medical benefit under the Insurance Acts. During that period the Royal Commission can inquire without distraction into the conditions under which this medical benefit can best be administered.

It is significant that just at this moment proposals have been made for creating a new system of health insurance in France. These proposals, which were described by our Paris correspondent last week, are as yet not elaborated in detail. French legislation tends to pass laws which are sometimes mere statements of general principles, the details of administration being left to be worked out by regulations made by the executive. Even in Great Britain, where this tendency is not so marked, the law of health insurance is not operated without a vast number of subsidiary regulations, so that no one, for example, could understand the relation of the medical profession to the State system under the National Health Insurance Acts without studying the latest medical benefit regulations. It is therefore not easy to judge of the French project until it reaches the stage at which the executive works out the details. As a matter of principle, however, it may be assumed that the State will not wish to wreck its scheme by estranging the good will of the medical men on whose coöperation its success depends. Remembering our own controversies on this side of the Channel, we shall watch with interest and sympathy the efforts of the *corps médical français* to preserve its independence and to secure a position which shall be safe from the pressure of outside influences. The financial arrangements of any scheme of national health insurance must depend on actuarial information of a kind not always at first available. It is stated that the only information of this sort in France is that acquired by the French mutual benefit societies, but it is doubtful whether the benefits given by those societies are on a scale comparable to those now proposed. The misfortune of the medical profession is that, when such financial arrangements are found to have been based on too optimistic a scale, there is usually an attempt to make a revision of them at the expense of the doctors. The profession, in fact, has to guard itself against three possible perils. First, it must protect itself from being asked to do something foreign to its wishes and traditions; professional confidence must remain sacred; a doctor must not be required to undertake the treatment of an impossible number of patients, nor can he be expected to act as magistrate and policeman towards the malingerer. Secondly, the profession must retain control of professional standards and of disciplinary decisions. Thirdly, the financial arrangements must provide a fair reward for work properly done. To fix a total of administrative cost and then, after various deductions therefrom, to leave the medical profession to an undignified scramble for remuneration out of a fluctuating balance—that is one way and the wrong way. The other way is first to fix the proper remuneration for the necessary professional services and treatment, and then to construct a financial scheme which shall secure the payment of that remuneration irrespective of other considerations. The medical profession in France, with its noble record of public service and of successful research, may be trusted to work the new proposals to the public good.

The new scheme may take a little while to mature. A *projet de loi* brought forward in France suffers many changes before it becomes actual law. Its initiator has much less control over its subsequent form and its progress through the legislature than has a Minister in charge of a Government Bill at Westminster. Two political considerations may perhaps also be mentioned. National health insurance has a German ancestry—a fact which not every nation will regard as a recommendation; and the patriotism which is preparing itself to lift the franc back to its normal exchange value may have to postpone schemes which make a further demand upon the public purse.

THE BETTING HABIT.

THE proposal to put a tax upon betting has drawn attention to the extent to which this form of gambling has become an organised part of social and economic life. Whether there is anything intrinsically wrong in making a bet is capable of vigorous but inconclusive argument; there can be no doubt as to the noxious results of the betting habit. The amount of money passing through the hands of bookmakers is by some people regarded as immaterial as far as the general community is concerned; it is only transferred from one set of pockets to another, but the amount of energy involved in the transfer may well be a matter of public concern. The maintenance of thousands of bookmakers, with their touts and assistants, the output of sporting prints, the postal work involved—in fact, the whole machinery of betting at best forms a luxury trade which in the end can scarcely be to the general advantage. At the worst it is a useless waste, involving continual loss to the class of habitual bettors and frequently leading to disaster and crime. It is a peculiarity of this betting system that the backer of a horse rarely bets with his fellows, but employs the bookmaker as an intermediary. In some countries the totalisator largely replaces the bookmaker, and a known percentage of the amount passing through the machine is deducted before the remainder is divided amongst the successful backers. In either case the result is a steady depletion of the funds of the habitual bettor. This being so, backing horses as a means of making money should not appeal to those accustomed to close reasoning, and yet it may be observed that a large amount of mental effort is spent by quite intelligent people in studying, pencil and paper in hand, that quality called "form" in an attempt to "defeat the bookies." The bookmaker, meanwhile, if he knows his trade, is invincible, and the only person defeated is the student of form or someone else pursuing an equally unreliable scheme for outwitting arithmetic.

The man who makes a casual bet or takes a share in a sweepstake presents no problem; that the breeder or trainer of racehorses, and those immediately connected with the industry, should make wagers seems a part of the business, though there are exceptions occasionally when one hears of people in this industry who never bet; and a visit to a race meeting with an incidental bet or two makes up a comparatively harmless day's recreation. But a feverish interest in betting for its own sake now possesses masses of people, and, since this interest leads only to loss of money and secondary disasters both in the home and in relation to employment, the causes for it must be sought elsewhere than in the sphere of conscious motivation. These causes can only be guessed at, but probably rest upon character traits common to mankind. The thwarted will to power that underlies many neurotic performances may find an outlet in pitting one's judgment against that of others, and the man who offers gratuitous "tips" to friend or stranger—often by the quaint process of writing them upon the wall of a public lavatory—may taste for a moment the sweets of superior knowledge. Pride or conceit, often a compensation for a feeling of inferiority, produces a belief that the individual concerned is not as other men, but can succeed when they fail. If these suggested motives seem too indirect, simpler ones may be sought in the power of example, the desire of getting something for nothing, or the craving for excitement. Whatever motives are suggested, however, frustrated desire appears in most of them. The contented man whose interests are satisfied is no more likely to fall a victim to the betting habit than to alcohol. We must conclude that the physical and spiritual surroundings of many people do not satisfy their needs, and that self-control and common-sense are too weak to withstand the tendency to seek escape from reality in the excitement and fantastic hopes of the gambler. This view accords with the evidence given before the recent Commission showing that the practice is most widespread in those classes where life is most dull. In considering the problem it is plain that we can be guided neither by those who boldly maintain that the desire to gamble is inherent in human nature nor by those who, inspired by the best intentions, would solve it by making betting a crime. The betting habit, like alcoholism, delinquency, and other sociological difficulties, cannot be solved by direct attack upon the symptom.

RESEARCH IN FOOT-AND-MOUTH DISEASE.

WHILE the immediate brunt of the epidemic of epizoötic stomatitis is abating, the desire to take advantage of its lessons is assuming more definite form. In our present issue Dr. J. A. Arkwright, of the Lister Institute, who was in charge of the research work on board ship in 1921, pleads for the faith and courage to set up and maintain a proper experimental station on land. Easy though it would be to leave research to countries where the disease is ever present, Dr. Arkwright points out with great cogency that the problems are not the same for our own country where means should be adapted to the protection of our insular position. Experimental study, already made difficult by the policy of slaughter, has been further impeded by the belief that rodents were immune to the virus. This statement by Löffler and his colleagues has now been set aside, and it has been shown that the virus can be kept active by passage through a series of guinea-pigs. We also print from the Liverpool Bacteriological Department a piece of work of the first importance on infected rats. To this department glands were brought from the carcasses of cows sent to the abattoir as non-infected but having been in contact with cases of foot-and-mouth disease. Prof. J. M. Beattie and Mr. David Pedden fed these glands to rats which developed œdematous swelling of the feet, vesicles between the toes, and patches of gelatinous œdema in the lungs. The special localisation of the lesions is that of the disease in cattle, apart from the condition of the lung, which has apparently not been described before. Should this work, which has analogies with the observations upon guinea-pigs by Waldmann and Pape, be confirmed, an important avenue for investigation is opened up in view of the infected rat as possible carrier of the disease. Moreover, as the authors point out, rats can be easily isolated and the risks of investigation reduced to a minimum. There is no doubt that the Board of Agriculture should consider resumption of the truncated work of 1921.

INDEX TO "THE LANCET," VOL. II., 1923.

THE Index and Title-page to Vol. II., 1923, which was completed with the issue of Dec. 29th, is now ready. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 1, Bedford-street, Strand, W.C. 2. Subscribers wishing to receive the Indexes regularly as published should indicate this desire.

Annotations.

"Ne quid nimis."

HOPE FOR THE LEPER.

A FORMAL campaign against leprosy is being inaugurated this week in London. The precise extent of the disease throughout the world is not known with accuracy, although there are probably about 500,000 lepers in India and twice as many in China. The northern section of the New World is comparatively free—Mexico being an unknown quantity—but in the southern republics, colonised from the Iberian Peninsula, only Chili appears to be free, and Colombia, a former centre of slave import, is credited with a high proportion of lepers. Missionaries state that Sao Paulo in Brazil has a higher comparative rate of non-segregated leprosy than any other city in the world. Oceania has some high rates, but Australia is free with the exception of the coastland of tropical and sub-tropical Queensland. Sir Leonard Rogers recently estimated the total leprous population in all countries at 2 million, or 3 million if the early cases are included in the calculation. Fortunately, the effectiveness of the chaulmoogra treatment is opening up great possibilities both for the individual and for the infected neighbourhood. Clinical improvement is by no means rendered void by the fact that pharmacologists have not yet been able to agree as to which of the constituents of chaulmoogra oil it is that possesses therapeutic value. Much still remains to be done in isolating the active ingredients. But the latest advances towards the solution of the problems of leprosy have been chronicled in our columns, and their story warrants the hopeful attitude adopted by the leaders of the new campaign.

Under the British rule, apart from India, leprosy has to be dealt with in the tropical African colonies, in Ceylon, the Malay States, Malta, and Cyprus, and the Imperial responsibility implied has led to the foundation of the British Empire Leprosy Relief Association, with the Prince of Wales as patron, and the Viceroy of India and the Governors-General of Canada, New Zealand, and South Africa as Vice-Presidents. Lord Chelmsford is chairman of the General Committee and Sir Leonard Rogers chairman of the Medical Committee. The aims of the Association are:

(1) To help all lepers in the Empire by providing the latest treatment for all, and houses for those who are homeless and destitute.

(2) To supply the latest medical information and the most improved drugs to leper institutions, settlements, and hospital clinics; and to train those in charge of lepers in applying the treatment efficiently.

(3) To support sound schemes of segregation, with the best treatment, in countries where large numbers of lepers ought thus to be dealt with.

(4) To collect information and statistics and to issue bulletins of information and advice to all working amongst lepers.

(5) To support further researches on both the ætiology and treatment of leprosy, with a view to discovering more efficient methods of prevention, and to further simplify, shorten, and cheapen the curative measures.

The movement is being formally launched at a Mansion House meeting as we go to press, where the speakers include Lord Chelmsford, Sir Humphry Rolleston, and Sir Leonard Rogers. The appeal should meet with a ready response in the light of the assurance given by Dr. E. Muir, working at the School of Tropical Medicine in Calcutta, who is able to state his belief that in all early cases the arrest and retrocession of the disease, up to a relative cure, may be expected if diet, exercise, and general sanitary conditions are favourable, and if the chaulmoogra treatment is continued for a sufficiently long period of time. In one of the large Indian asylums the mortality has already been reduced to one-fifth of its former rate. Reports in the quarterly magazine of the Mission to Lepers repeatedly mention the special treatment and the new atmosphere which its application is bringing into leper colonies.

THE TREATMENT OF INCOMPLETE FEBRILE ABORTION.

SOME recent papers, contributing statistical evidence on behalf of the conservative, expectant treatment of incomplete febrile abortion, would suggest that the superiority of this course over the routine immediate evacuation of the uterus was established. But as recently as 1922 the well-known German gynæcologist, Prof. A. Döderlein,[1] of Munich, expressed himself as follows: "I regard it as a fatal heresy to recommend expectant treatment in febrile abortions." Prof. Döderlein's views, it may be remembered, were those of unchallenged orthodoxy less than a generation ago, and when Prof. G. Winter, of Königsberg, ventured to plead for expectant rather than active treatment some score of years ago the opposition he encountered was formidable. He has, however, repeatedly returned to the charge, and in his most recent publication [2] he is supported by an impressive show of statistics. He finds that this controversy has yielded 267 original articles, dealing with about 24,000 febrile abortions. Among 276 cases treated on expectant lines there were 178, or 64·5 per cent., in which abortion was terminated spontaneously. It was also found that among 6512 cases of abortion treated by digital evacuation the mortality was 2·9 per cent., whereas among 1048 cases in which abortion was completed spontaneously the mortality was only 1 per cent. Prof. Winter thinks bacteriologically in this matter, and he has come to the conclusion that the fate of the patient largely depends on the nature of the infecting organism. He has collected the 2080 cases reported by 21 observers publishing their bacteriological findings, and he has found that the mortality ranges from 7·3 per cent to 20·8 per cent., according to the nature of the infecting organism, hæmolytic streptococci being the most toxic. He suggests that, whenever it is possible, a bacteriological examination should be made of the vagina, and that when hæmolytic streptococci are found no attempt should be made to evacuate the uterus till they have disappeared. In the absence of a bacteriological examination he urges that evacuation of the uterus in the febrile stage of an abortion should not be attempted forthwith, and when expectant treatment is not followed by the spontaneous expulsion of the ovum evacuation of the uterus should be with a blunt curette rather than with a finger.

Prof. Winter has had many followers, one of the earliest being Dr. Emil Bovin, of Stockholm. His last paper [3] on this subject contains a statistical analysis of the 1141 cases of incomplete febrile abortion treated at his hospital up to Dec. 31st, 1922. Though the period under review included the pandemics of influenza and the deprivations of the late war, he had to record only 24 deaths (2·1 per cent.). In 623 cases the abortion was completed spontaneously, the mortality being only 1·3 per cent. Among the 518 cases in which expectant treatment had to be given up and evacuation of the uterus performed there were 15 deaths, or a mortality of 2·9 per cent. There were considerable differences in the results according as evacuation was performed during, or some time after, the febrile stage; the mortality was 1·9 per cent. in the latter class, and as great as 8 per cent. in the former. Like Prof. Winter, Dr. Bovin has found that giving quinine frequently by the mouth for a few days favours the spontaneous completion of an abortion. During the three years 1920–22 expectant treatment alone was successful in 241 out of 366 cases of febrile abortion (65·8 per cent.), partly, at any rate, owing to the use of quinine. However conflicting opinions may be as to the best course to pursue in the treatment of incomplete febrile abortions, there seems to be little doubt that most of them represent criminal acts. It is, of course, often difficult to obtain reliable information on this point; much depends on the desire and ability of practitioners to elicit information from their patients. In this connexion Dr. Bovin refers to investigations published

[1] Deut. med. Woch., Jan. 5th, 1922.
[2] Ibid., Dec. 21st, 1923. [3] Hygica, Dec. 31st, 1923.

in 1922 by Dr. Richter, of the Swedish Allm. Barnbördhuset. Among the 107 women admitted to hospital between September, 1920, and April, 1921, suffering from febrile abortion and a temperature exceeding 38° C. there was not one who failed to admit that criminal abortion had been attempted.

THE PREVENTION OF STREET ACCIDENTS.

STATE medicine is a wider subject than public health, for it has its forensic as well as its preventive side; but neither of these titles in their ordinary acceptation in this country comprises the prevention of accidents from machinery or from traffic or otherwise. Thus outside the sphere of activities of local sanitary authorities and county councils—and never hitherto proposed to come within the control of the central Ministry of Health—there lies preventive work of great public importance, by the execution of which much loss of life and many minor injuries might be obviated. Of such work the prevention of accidents forms a most important part. Its importance is brought home to us by a valuable report of the American National Safety Council on "The Warning of Public Accident Statistics." The work of this Council illustrates to how great an extent in the States important public health functions are being carried out by voluntary associations. It is not surprising to find that large accident and life insurance societies and traffic engineers of railways and large industries form the Accident Statistics Committee of the Public Health Section of this National Safety Council.

The statistics displayed by them are startling. In 1922 there occurred 75,300 fatal accidents in the United States; the number would have been 35,000 to 40,000 fewer if they had occurred on a scale according with the experience of England. Of this number the automobile was the chief cause of fatal accidental injury, and accounted for 18 per cent. of the total accident budget. This increase is the more noteworthy in view of the fact that the automobile death-rate was 24·0 in 1915 and 11·6 in 1922 per 10,000 automobiles registered. The regulation of automobile traffic has improved, but the mass of destruction of life has nevertheless augmented. It is noteworthy, further, that the automobile death-rate per 10,000 automobiles registered varied from 2·98 in Chicago, 2·90 in New York, and 1·05 in Los Angeles to 0·47 in Salt Lake City. The question remains as to whether the blame for these great variations in death-rate is due to carelessness of pedestrians or of chauffeurs, or to variations in the permeability of streets and the regulation of traffic. The report in hand does not profess to answer these important questions in detail, but it gives most valuable information throwing light on them; and it serves, further, as a remarkably excellent example of the fact that statistics carefully collected and intelligently analysed may give a valuable lead on problems of life-saving. In the cities for which statistics are given children under 15 years of age formed on an average 37 per cent. of the persons killed. In the city of New York they formed 50 per cent. These figures clearly indicate that it is not merely additional precautions on the part of the pedestrian that are needed, but that additional safeguards are called for to protect him. The Committee lays stress on the importance of traffic movement studies in showing how to diminish automobile fatalities. The first essential is the preparation for each town of a "traffic-artery" map, which usually would show possibilities of diversion of traffic on a considerable scale. The Committee's definite conclusion is that in most cities traffic congestion is due to the ineffective use of street areas rather than to the lack of them. We wonder whether even in London the police authorities could show that the present deplorable amount of traffic congestion is not capable of being materially reduced by application of this axiomatic statement. The next point which is stressed is the importance of each city maintaining spot-maps of traffic accident occurrence, by means of which an approach might be made to a determination whether the troublesome nature of the road itself or the lack of traffic discipline is more to blame. Such spot-maps form the first line of guidance in control and diversion of congested traffic.

We have merely indicated a few of the many important points comprised in this valuable report, which should be studied by all interested in this problem. The prevention of accidents, especially now that automobile accidents are becoming increasingly a serious cause of death, is of interest to all medical men; the proper control of traffic and the reduction of congestion at certain points concerns them as busy messengers of health intent on carrying out their mission in life.

A NEW TEST FOR TYPHOID FEVER.

Dr. E. Moretti,[1] of the Ospedale Maggiore, Milan, has devised the following modification of Petzetakis's iodine reaction for the diagnosis of typhoid fever. 25 c.cm. of urine are saturated with 20 g. of crystallised ammonium sulphate. After about a quarter of an hour the urine is filtered and diluted to about a third if it is too thick. To 10 c.cm. of the filtrate one-fifth of its volume of a 10 per cent. solution of sodium hydrate is added, and then a drop of a 5 per cent. tincture of iodine. The solution is then shaken, and if the reaction is positive a persistent golden-yellow colour is produced. Out of 100 cases of typhoid fever in which this test was tried, it was positive in 95 and negative in only 5, which were remarkably mild cases in which the temperature became normal at the beginning of the third week. In two cases of paratyphoid A the reaction was negative, while it was positive in two out of three cases of paratyphoid B. In the great majority of all the typhoid cases the reaction was positive in the first week, and very frequently during the first few days of the disease. The intensity of the reaction increased until the disease reached its height and then gradually decreased as the symptoms subsided, the reaction becoming negative before the temperature reached normal. The reaction was also invariably positive in pulmonary tuberculosis with cavity formation, very frequently (80 per cent.) positive in cases in the second stage, and occasionally (20 per cent.) positive in the first stage. It was often positive during the height of pneumonia and measles, and always negative in malaria and acute rheumatism. The iodine reaction is thus positive in the same diseases as the diazo-reaction, and like it is an expression of an increased elimination of urochromogen. It is of greater diagnostic value than the diazo-reaction owing to its earlier appearance, greater constancy, and longer duration. In Dr. Moretti's cases the diazo-reaction was positive in only 78 per cent., and, as a rule, did not become so until the first half of the second week.

THE HISTORY OF PERCUSSION AND AUSCULTATION.

IN another column we publish an abstract of an address delivered by Sir William Hale-White before the Midland Medical Society upon the History of Auscultation and Percussion. Broadly speaking, we may say that these methods of diagnosis did not come into use until the beginning of the nineteenth century, and, though Hippocrates knew the succussion splash, until the discovery of the X rays in 1895 auscultation and percussion remained the sole means by which the physician could form any opinion as to the conditions existing within the chest, other than the nature of the sputum. It is easy to be wise after the event, and when we read the treatises of Auenbrugger and Laënnec to say "Why did no one think of this before?" Auenbrugger was born in 1722 and Laënnec died in 1826. For nearly the whole of these hundred years Europe was convulsed by wars, and there was no soldier who beat the ground with a

[1] Riforma Medica, Nov. 19th, 1923.

musket-butt to ascertain the presence of a cavity which might be a mine, or who, in the same way, knocked a cask to ascertain whether it were full or empty, or partially so, or who listened with his ear to the ground for the approach of cavalry, or to hear the scraping of a shovel or a pick by approaching miners, who was not practising and profiting by auscultation and percussion. Some army surgeons of the time must have seen these practices or even have taken part in them themselves, and yet to none did it occur that if a partially filled cask gave a different note above the level of the fluid, to that which it did below, the same law would hold good for the presence of fluid in the chest; or that if the scraping of a pick or shovel could be heard, the scraping of two roughened surfaces within the chest could also be heard. Until the advent of the two men who had ears to hear the medical profession made no use of what in other fields of activity was common knowledge. Both the treatises of Auenbrugger [1] and Laënnec,[2] the latter with biographical notes by Sir William Hale-White have been recently reprinted, and rendered accessible to English readers.

A SYLLABUS FOR SCHOOL SCIENCE.

HARDLY anyone is satisfied with the present state of science teaching in schools, and the recent attempt by the General Medical Council to push chemistry and physics back into the school period has made the questions involved of more immediate professional interest. The difficulty seems to be this. Schoolboys are too immature to get any real advantage from the natural sciences, as ordinarily taught, because they cannot apprehend the generalisations which alone give the subjects as such any real meaning, and the common discipline of experiment, observation, and verification thereby becomes a barren and uneducative toil. Biology seems in a distinctly better position than chemistry because its general ideas are not difficult for young people to grasp, but as a matter of fact biology is much less, and possibly worse, taught in schools than the other subjects. Those who have taught science in schools have tried to apply the methods suitable for university students with the addition of as much water as they deem necessary, and the result is so mawkish and unsatisfactory that many college teachers have expressed their preference for boys who have not "done stinks" at school. As a leading article in *Nature* (Jan. 26th, p. 113) points out, the vicious circle is completed by the fact that the precise scope and mode of school science are really determined by those of the matriculation examinations imposed by the universities.

The writer in *Nature* makes out a strong case for the substitution of "general science" for the formal procedures which obtain at present—for a course, that is, which will give the schoolboy some idea of how the world works and which will whet the appetites of a certain number to go on further and deeper when they have the chance. And being constructive as well as critical he sets out a guiding syllabus for such a course taken from the Book of Wisdom:—

> Knowledge of the things that are, namely, to know how the world was made, and the operation of the elements.
> The beginning, ending, and midst of the times; the alterations of the turning of the sun, and the change of seasons.
> The circuits of years and the positions of stars.
> The natures of living creatures, and the furies of wild beasts; the violence of winds, and the reasonings of men; the diversities of plants, and the virtues of roots.

Even the wisdom of Solomon is not fool-proof, and there are loopholes here for the naughtiness of the astronomer who wants to make his subject a peg for computation, and of the botanist whose chief interest in a root is to know when it is not a root. But something of this kind in good hands would surely lay a more satisfactory foundation for medical education than the present imitation of grown-up knowledge. The experiments in teaching such general science which have been made in America, and the text-books which have been produced there, seem clearly to show the possibility. One danger alone is obvious, and that is a very real one: there must be no idea that "general science" is a royal road to knowledge. Properly used it hardly arrives at knowledge at all; it is a sort of map on which the student may see what places exist and get some indication of how to get there. Like more earthly maps, it will encourage dreams of happy journeys.

GEOGRAPHICAL DISTRIBUTION OF PROSTATIC HYPERTROPHY.

Dr. E. Pfister,[1] of Dresden, remarks that while geographical differences have long been recognised in regard to other urological diseases such as calculus the literature on the geographical distribution of prostatic hypertrophy is very meagre. Most of the data have been derived from warm countries only such as Egypt, Japan, Southern China, India, and the Philippine Islands. The experience of Dr. Pfister, who was for many years physician at the Deaconess Hospital at Cairo, agrees with that of other surgeons who have practised in Egypt, that hypertrophy of the prostate is much rarer in that country than in Europe. Kitagawa and Takagi, whose observations were based on post-mortem studies and not merely on clinical examination, reported similar results in Japan. Hypertrophy of the prostate appears to be less prevalent in the Philippines than elsewhere, as Dill had never observed a case in the large number of patients at the Philippine General Hospital at Manila. J. O. Thomson states that the condition is rare in Southern China, and according to Kenneth M. Walker it is infrequent among the inhabitants of India. Buschan and Ruge have found that it is also rare among negroes in whom, as Dr Pfister had shown in 1913, calculus is also uncommon. On the other hand, it is noteworthy that in the Tirol, where goitre is endemic, hypertrophy of the prostate is frequent. This association finds its analogy in dogs in which hypertrophy of the prostate is often accompanied by goitre. In any case inflammation does not appear to be causally connected with enlargement of the prostate, as gonorrhœa is exceedingly prevalent in those countries in which hypertrophy of the prostate is rare, and in Egypt, where bilharzia frequently causes inflammation of the prostate, hypertrophy of the organ is very uncommon.

[1] Urological and Cutaneous Review, December, 1923.

THE RÔLE OF THE SPLEEN IN THE PRODUCTION OF IMMUNITY.

FROM many sides evidence accumulates of a new movement amongst those workers in physiological and pathological fields whose chief interests are concerned with problems of immunity. The rich promises of the epoch which began with Pasteur have not been in every respect fulfilled, the brilliant results of the discovery of the development of antibodies after the inoculation of some micro-organisms must be set off against the disappointments which have followed the most painstaking endeavours to secure immunity in the case of certain other infections. Impressed by such failures there is a growing group of workers who are seeking to elucidate immunological problems from a different point of view. An example of such work is to be found in the paper by Dr. Ivan I. Manoukhin which was published in THE LANCET of Jan. 26th. In this article the author records the remarkable successful results he has obtained by the application of X rays to the enlarged spleens of a large number of cases of chronic malaria. The cases treated included tertian, quartan, pernicious, and mixed infections and the results appear to have been remarkably successful. Dr. Manoukhin is at pains to emphasise that his successes have been especially in that group of cases in which induration and fibrosis of the spleen were least marked, an effect which he explains on the basis of a theory that irradiation of the spleen

stimulates what he terms the "leucocytolytic" properties of that organ. Without dwelling further on what must admittedly be at present an hypothesis not yet fully proven, we would direct the attention of our readers to this work as evidence of those still obscure relations of the spleen to immunological processes. It must surely be true that future developments will bring new and useful information from inquiries of this nature. As a further example of current work pointing in a similar direction we may quote a recent paper[1] by W. S. Lazarus-Barlow and R. H. Parry, who showed that the introduction of grafts of Jensen's rat sarcoma into the splenic tissue of rats produced a higher general resistance to subsequent subcutaneous inoculation with the tumour than if immunisation were attempted by intracranial or subcutaneous introduction in the first place. They further showed that intrasplenic inoculation definitely retarded the growth of an established subcutaneous tumour in the rat, even though actual disappearance of the tumour was not achieved. These facts cannot, we believe, be fully explained by any existing theories of splenic function; that they are still inexplicable is not the least promising feature in these interesting observations.

THE SLIT-LAMP IN OPHTHALMOLOGY.

SOME years ago Dr. Gulstrand, a Swedish ophthalmologist, invented a new method of illuminating the anterior parts of the living eye, by means of which, combined with a binocular (so-called) corneal microscope, it is possible to observe structures which by the methods hitherto in ordinary use cannot be seen. The apparatus consists of a strong light focused on any desired part of the eye by a system of lenses through an adjustable slit, producing a prism-shaped area of illumination which, viewed with a binocular magnifier of about 24 diameters by the dark-adapted eyes of an observer, displays such objects as the nerve fibres in the cornea or the blood corpuscles circulating in the corneal vessels. The apparatus is somewhat expensive; its routine employment in the consulting-room would materially add to the time necessary for examining a patient, and to acquire facility in its use requires about as much practice as that necessary to become at home with the use of the ophthalmoscope. Nevertheless, its importance as an aid to scientific diagnosis is great, and it is believed by some that its introduction will mark a new era in ophthalmology, comparable to that opened by the invention of the ophthalmoscope itself. In the December number of the *British Journal of Ophthalmology*, Mr. Harrison Butler gives an account of a special week's course on the subject, held at the University Eye Clinic at Zurich by Prof. Alfred Vogt, who has also published an atlas of slit-lamp microscopy. It can hardly be expected that the practical clinical discoveries from the new method can be very striking as yet, but Vogt claims that the earliest clinical sign of sympathetic ophthalmia is the appearance of clusters of cells in the aqueous which can only be seen by this method. Perhaps the most promising field of discovery is the lens, a complete section of which can be illuminated by this method, displaying the exact localisation of opacities. So far English ophthalmologists have been somewhat behind their continental colleagues in taking up this subject, but the interest shown in the method at the meeting of the Ophthalmological Section of the Royal Society of Medicine, reported on p. 231, is encouraging. At this meeting drawings of the appearances seen were shown by Mr. Butler and by Mr. Basil Graves, a Lang Research Scholar. For examining the fundus of the eye the slit-lamp is only available when combined with a contact lens which abolishes the refraction of the cornea, a method which has been worked out by the German ophthalmologist Koeppe, who employs a linear magnification of 80,[2] but which is not practicable at present for every-day clinical work.

THE CONTROL OF TUBERCULIN.

WHATEVER other effect, for good or for evil, tuberculin may produce when injected into the human or animal body, it certainly does produce tolerance of itself. In the case of the human subject patients have received as much as 1 c.cm. or more of Koch's old tuberculin week by week for months or years without perceptible reaction, and in the case of cattle this tuberculin tolerance has been put to improper use. Pedigree cattle are not allowed to enter many countries unless they have passed a tuberculin test to prove their freedom from tuberculous infection; unscrupulous dealers are known to have given preliminary tuberculin injections to infected cattle in order that they may successfully pass the test. The manœuvre has also been tried in order to outwit a stock owner who rightly insists on the test being applied prior to purchase. At the present moment this fraudulent procedure can only be countered by prescribing a period of isolation and quarantine prior to the official application of the tuberculin test. The evil has attained sufficient importance to justify the Federation of Medical and Allied Services in taking action. A resolution was submitted to the Medical Council of the Federation last Tuesday by Prof. F. Hobday, on behalf of the Veterinary Medical Association, to the effect "That the sale of tuberculin and its use for diagnostic or medicinal purposes shall be restricted to members of the medical and veterinary professions." The demand for legislation to bring the sale and use of tuberculin under Government control is supported by the Agricultural Committees of County Councils throughout Great Britain as well as by the National Veterinary Association, but is opposed by the National Farmers' Union. It is felt that the control of tuberculin is the keystone of the whole edifice of the Milk and Dairies Act, for in controlling tuberculin the most dangerous and most frequent contamination to which milk is subject could also be controlled. Under the Coal Mines Act mallein can only be used under strict supervision, and glanders has practically been eliminated in this country. The legislation suggested by the Federation, by doing away with misuse of the tuberculin test, would be a step towards eliminating tuberculosis in cattle and obtaining a tubercle-free milk supply.

AN UNUSUAL CASE OF STREPTOCOCCAL SEPTICÆMIA.

AT a recent meeting of the Medical Society of the Paris Hospitals MM. Cain and Oury[1] reported a case of fatal streptococcal septicæmia in a man aged 32, in whom the lesions were strictly localised in the veins of the right upper arm and left deep femoral vein, and presented all degrees of severity—viz., suppurative phlebitis with periphlebitic abscess on the one hand and more or less old-standing and organised phlebitis on the other. In contrast with the severity and variety of the venous lesions was the normal condition of the heart, liver, and kidneys in spite of the profound intoxication. Histological examination confirmed the clinical findings. The streptococcus had not formed any colonies in the viscera, but was found in them only in the form of emboli, which had not produced any reaction in the neighbouring tissues, and had probably only occurred at the moment of death. The phlebitis constituted the whole disease, and the condition was one of acute venous septicæmia without a known portal of entry, being caused by a streptococcus of attenuated virulence, as was shown by absence of deep lesions in the organs and lack of virulence for animals. Death, which took place after about a month's illness, was due to broncho-pneumonia. Only a few similar cases have been recorded. Renault and Lévy in 1912 reported a case of streptococcal infection with localisation in the veins and small joints which ended

[1] Bulletins et Mémoires de la Société Médicale des Hôpitaux de Paris, Dec. 13th, 1923.

in recovery, and Roux in 1919 published a fatal case of prolonged septicæmia, which ran its course in two stages, the first being one of subacute and the second of acute venous septicæmia. The streptococcus is not the only organism which may give rise to primary venous localisations. The typhoid bacillus may produce similar symptoms, as was illustrated by three cases recently reported by Etienne.

THE PATHOLOGY OF ANAPHYLAXIS.

THE symptoms and pathology of anaphylactic shock differ a great deal in different animals. The classical guinea-pig reaction, in which bronchiolar spasm often leads to death by asphyxia, is quite exceptional. There are reasons for thinking that the reaction in the dog is fairly similar to what happens in man. Fatal human cases are quite rare, and have generally not been at all fully investigated. We welcome, therefore, the careful study of anaphylactic shock in the dog, which Prof. H. R. Dean and Dr. R. A. Webb contribute in three papers in the current number of the *Journal of Pathology and Bacteriology* (pp. 51–94), the other contents of which are summarised on p. 237. Dogs, like men, are rather insensitive. A certain number show no symptoms on receiving the second dose of foreign protein (in this case horse serum), and only a small proportion die. Symptoms of shock, if present at all, come on at once; the animal vomits and lies down with general muscular relaxation. This does not often last more than half an hour, after which signs of recovery are seen. Recovery may be permanent, or a second period of collapse with great weakness and stupor may supervene, which may end in death or last for several hours, after which the animal slowly recovers. The most obvious anatomical change observed is an extreme congestion of the liver and gall-bladder. The liver swells very much and becomes deep purple, the engorgement being due to a distension of the sinusoids with hæmorrhage between the liver-cells; in severe cases the liver-cells themselves show degenerative changes and necrosis of extraordinarily rapid onset. In more than half the animals cardiac hæmorrhages were found, which in several instances involved a branch of the auriculo-ventricular bundle, but there is no evidence that these contributed to the symptoms or the fatal result. In a few instances hyper-distension of the lung alveoli was found with hæmorrhage; in the other organs no gross changes were observed. The changes in the blood were worked out in considerable detail. In both normal and sensitised animals an intravenous injection of horse serum leads to a temporary concentration of the blood. In sensitised animals this is followed by a much greater and more lasting rise in the red corpuscles per cubic millimetre and the percentage of hæmoglobin, due, doubtless, to the passage of plasma into the tissue spaces, and accompanied, curiously enough, by a fall in the colour index and the appearance of large numbers of nucleated red cells in the peripheral blood. Simultaneously with the onset of shock the blood everywhere becomes extremely venous, and this continues in spite of vigorous artificial pulmonary ventilation. The mechanism of this is quite obscure, unless it be an obstruction to the exchange of gases in the lungs by an exudation of plasma into the walls of the alveoli, but the authors attribute to the defective oxygenation of the central nervous system a main share in the production of the lasting and sometimes fatal symptoms. The immediate symptoms are caused by a fall of blood pressure, largely due to the loss of effective circulating blood in the liver. Another blood change, better known from previous work, is the leucopenia which follows immediately after the serum injection and lasts half an hour or so, to be succeeded by a marked leucocytosis. An exemplary analysis of the phenomenon shows that it is due to the polynuclear cells being caught in the lung capillaries.

PNEUMOCOCCAL INFECTION WITHOUT PNEUMONIA.

AT a recent discussion of the Manchester Pathological Society the view was expressed[1] that lung infection with the pneumococcus of pneumonia is an air-borne infection and not blood-borne. Experimental proof of this view is afforded by the occurrence of cases in which there is a prolonged, and often severe, infection of the blood, involving close contact between the lungs and the infecting pneumococcus and yet pneumonia does not occur. Such a case has been recorded by Dr. A. R. Felty and Dr. C. S. Keefer,[2] of the Biological Division of the Medical Clinic, Johns Hopkins University and Hospital, who preface their account of it by stating that while the pneumococcus is frequently found in the blood stream during lobar pneumonia, as is shown by the fact that 25 per cent. of Cole's cases gave positive cultures, pneumococcæmia in the absence of a primary pneumonia, with or without subsequent involvement of the lungs, meninges, endocardium, or joints, is much less common. They record an illustrative case in a previously healthy woman aged 22, who suddenly developed severe constitutional symptoms of a general infection without at first presenting any signs of a localised focus. Repeated physical and X ray examination of the chest failed to show any evidence of a pneumonic process, but a generalised blood infection by Type 1 pneumococcus was demonstrated, and its source was determined by cultivation of the purulent discharge from the posterior pharynx and ethmoid cells. On active treatment of the local infection and specific serumtherapy rapid recovery took place. The writers allude to similar cases of primary pneumococcus infection, some of which have run a mild course like their own, while others have ended fatally, and lasted as long as one or two months simulating at first typhoid fever. When metastases did not occur in the joints, lungs, endocardium, or meninges the outcome was usually favourable. In conclusion, the writers emphasise the frequency of a focus of infection in one or more of the paranasal sinuses in these cases of pneumococcal sepsis, and allude to the investigations of Darling who found in a series of necropsies on all types of pneumococcal infections that 92 per cent. showed pneumococcus inflammation of the paranasal sinuses, and four out of five patients with pneumococcal sepsis had pneumococcal sinusitis. This case bears out, in the human subject, the experimental results obtained in monkeys, animals susceptible to pneumonia, in which the introduction of pneumococci into the air-passages causes pneumonia, while their injection into the blood-stream, or subcutaneous tissue, produces a general septicæmia without lung involvement.

[2] Journal of the American Medical Association, Nov. 10th, 1923.

NOTIFIED INFECTIOUS DISEASES.—During the week ended Saturday, Jan. 19th, there were notified to sanitary authorities in England and Wales the following cases of the commoner infectious diseases: scarlet fever 1501, diphtheria 792, enteric 17, pneumonia 1220; and of the less frequent diseases: puerperal fever 45, cerebro-spinal fever 9, acute poliomyelitis 8, acute polio-encephalitis 1, encephalitis lethargica 18, continued fever 1, dysentery 8. Of small-pox 77 cases were notified from the following areas: Derbyshire 26 (Bolsover 2, Chesterfield 8, Ilkeston 2, Swadlincote 5, Blackwell R.D. 4, Clowne R.D. 1, Shardlow R.D. 4); Durham 1 (Chester-le-Street); Gloucestershire 15 (East Dean R.D.); Leicester 6 (Ashby-Woulds); Notts 27 (Hucknall 10, Kirkby-in-Ashfield 15, Stapleford R.D. 2); Yorks, West Riding 2 (Adwick-le-Street 1, Bolton-upon-Dearne 1). Groups of cases of ophthalmia neonatorum were notified in the metropolitan boroughs of Battersea, St. Pancras, and Southwark 2 each, in Birkenhead 3, Sunderland 2, Bristol 4, Liverpool 9, Manchester 7, Oldham 2, Willesden 2, Newcastle-upon-Tyne 2, Tynemouth 2, Nottingham 2, Stoke-on-Trent 4, Walsall 2, Cannock 2, Croydon 3, Birmingham 13, Sutton-Coldfield 2, Kingston-upon-Hull 2, Leeds 2, Sheffield 7, and Cardiff 3.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

LVI.—SQUINT IN YOUNG CHILDREN.

A SQUINT in a young child is of importance not only on account of its unsightly deformity and its association with errors of refraction and defective vision, but also because it is not infrequently an indication of organic nervous disease. This relationship at once suggests the primary classification of strabismus into two main classes—concomitant and paralytic. They have nothing in common, and it is the first duty of the practitioner to decide to which class the case belongs; for one is within the province of the ophthalmologist, whereas the other is the concern of the neurologist. The differential diagnosis is as a rule easy. In concomitant squint the two eyes move together to the same degree, the angle between them remaining more or less constant, nor is there any limitation of movement. If the eyes be alternately shaded the shaded eyes converge or diverge to the same extent. These children rarely complain of double vision. If, on the other hand, there is a paresis or paralysis of one or more eye muscles, the paralysed eye may show a limitation of movement in one direction. The eyes do not move together to the same degree, and if they be alternately shaded it will be noted that the secondary deviation is greater than the primary. Children suffering from paresis of an eye muscle generally, but not always, complain of diplopia. In doubtful cases the best test for children is that recently brought out by Hess, professor of physiology at Zürich. The apparatus is simple, consisting of a black sheet of cloth about 18 inches by 24 inches. To this are attached nine red wafers about half an inch in diameter, arranged in three parallel rows. The child is given a black rod, at the end of which is a green arrow; a red glass is placed before the fixing eye and a green one before the squinter. The child now sees the red wafers only with the fixing eye, and the green arrow with the squinting eye. We ask him to place the arrow on the wafers beginning at the top one of each row. If there be a paresis of a muscle, say of a lateral rectus, he will succeed in locating the wafers on the side opposite to the paralysed muscle, but he will fall short of the middle rows of wafers, and very far short of the row on the side which brings the weakened muscle into play. This simple test is within the capacity of almost any child, and gives us a definite measure of the amount of loss of function. If the result be charted and the test repeated from time to time, a graphic record of the progress of the case is obtained.

If tests show that there is no actual paresis of a muscle we are dealing with a concomitant strabismus, which may be convergent or divergent. Cases in which the deviation is upward or downward are uncommon; a strongly converging eye may turn up, but the treatment of the convergence includes that of the secondary error.

Concomitant Convergent Strabismus.

This type is far more common among the working-class children than in the upper classes. I have no doubt that heredity exerts a powerful influence in the ætiology of squint. In many cases among those who come to my school clinics one parent squints, and in a much larger proportion brothers and sisters are affected. I see no reason to doubt the view held by Javal, Worth, and others, that the essential cause of squint is hereditary lack of development of a fusion centre in the brain. Many children, examined with the amblyoscope and stereoscope, show no sign of any desire for fusion, and in others the faculty is feeble. It is obvious that if there be no desire for fusion the eyes have no directing force towards any given object. Again, if one eye is better than the other from the visual standpoint, that eye will be used for fixation to the entire neglect of the other, which may not only assume a false position but may deteriorate in function. A child is not born with a fully developed fusion faculty, but when it is six months old it has a fair grade of binocular vision. There are many adults who do not squint but who never can get the solid effect with the stereoscope, and often have difficulty in fusing the images from a field-glass. The deciding and ultimate factor in concomitant converging strabismus is generally hypermetropia, since there is an intimate relationship between accommodation and convergence.

In addition to the lack of fusion faculty and to mal-coördination of the neuromuscular apparatus there may be a mechanical element which helps to maintain a convergent squint. This is especially true of squints of high degree which have persisted for some years, for there is a tendency for the conjunctiva and the capsule of Tenon to develop on the inner aspect of the globe only to the extent demanded by the false position of the eye. This factor probably accounts for the failure of many operations and to counteract it some surgeons perform a plastic operation upon the conjunctiva. Again, the external rectus may be a very feeble attentuated structure or the internal rectus abnormally tight and strong. In this case an advancement alone will fail to correct the convergence, the internal rectus must be attacked.

Age of Onset.—During the first six months of life, when binocular vision is not fully developed, the child often shows occasional strabismus, but after this epoch any malposition of the eyes, especially if constant, should awaken suspicion. In most cases the history is that the child began to converge at about 3 years old, after an illness such as measles and whooping cough. The explanation probably is that the debility caused by the disease weakens the muscle-nerve mechanism which was before only just able to overcome the tendency towards abnormal convergence.

Amblyopia.—Frequently the squinting eye has very poor visual acuity, even after the most accurate correction of errors of refraction. Amblyopia may exist in varying degrees; the acuity of the average amblyopic eye is 6/60ths. In some cases it is congenital and may or may not be accompanied by strabismus, but mostly it is acquired, the so-called "*amblyopia ex anopsia.*" The explanation is that the child rather than see double has suppressed the image from the errant eye, and constant suppression has resulted in loss of function. Amblyopia develops rapidly in children under 3 years old and it is this complication which makes early treatment essential.

Non-operative Treatment.

There is a strong tendency towards spontaneous cure in concomitant convergent strabismus; probably the majority of squints disappear without treatment. Unfortunately, in many cases the eye "dies cured"—hopelessly amblyopic. Our methods must aim at the prevention and cure of amblyopia and the correction of the deformity. As soon as a baby is seen to have developed a permanent or even frequent squint treatment must begin. The first step in all cases is a careful estimation and correction of any error of refraction. The spectacles which correct the hypermetropia must be worn constantly. In a young child it may be difficult to determine the amount of vision in each eye. In such, if the strabismus is confined to one eye, I assume that this eye is amblyopic and occlude the other eye till the squint alternates from one eye to the other. As soon as I obtain alternation I assume that the eye is not amblyopic and give up occlusion, only to return to it if the strabismus shows any tendency to favour one eye above its fellow. Occlusion must be complete so as to exclude light. Merely to place a blank before the fixing eye is useless. The best way is to sew a pad of Gamgee tissue inside the spectacles, but if this be not sufficient to close the eye, then strapping must be used. As soon as alternation appears it is sometimes useful to put a little atropine ointment into the better eye on alternate days. Babies wear special spectacles

with short sides tied behind the head with ribbon. No child is too young to wear a correction for hypermetropia if he be a squinter, in fact it is criminal to neglect a case in this stage when we have the best conditions for preventing the onset of amblyopia. Older amblyopic children are handled in the same manner, but after 5 years of age the prospects of cure are much less and treatment often fails.

Can we do anything to educate a defective fusion sense? Much has been written and little done in this direction. The main difficulty is that the education must commence early, not later than 3 years old in most cases, and the process at such a tender age is intensely difficult, and demands more patience on the side of both parents and children than we can usually command. The methods employed are outside the scope of this paper. The results from fusion training are very disappointing, success infrequent, and often transitory. Probably those patients who regain fusion would have done so without the training after their visual acuity had been improved by spectacles.

Operation for Squint.

When a squinter has received treatment, for some years in the case of moderate degrees, and for at least a year in any case, operation will have to be considered. I find that the most suitable age for operation is 8. It is generally fairly easy to operate upon a child of 8 under local anæsthesia. Younger children are apt to be troublesome, and older ones still more so. All depends upon temperament and early home training. For the majority I find that a general anæsthetic is not necessary, it adds to the difficulties, and makes it impossible to judge the primary effect of the operation. I instil a few drops of cocaine and then inject a few minims of codrenine or novocaine with adrenalin under the conjunctiva over the muscles to be treated. This gives a painless operation if care be taken not to drag on the muscles with the squint hook.

There is great difference of opinion as to the best operation for squint. In any case, simple tenotomy of the internus should be avoided. It is unscientific and uncertain, and in many cases is followed by weakness of the converging act, and not infrequently by actual divergence of the eye. My own practice is to perform recession of the median rectus and advancement of the lateral. In recession the muscle is separated from its insertion into the globe and sutured to the sclera about 5 mm. further back. In advancement the rectus is separated from its insertion and re-attached to the limbal region.

The results of squint operations judged without optimism are not wholly satisfactory. It is very difficult to get a firm grip for the advancement sutures and not infrequently they cut out on about the third day and the muscle slips back to its old position. Probably about 50 per cent. are completely successful, another 30 per cent. good, leaving about 20 per cent. of poor or bad results. There is a tendency for the completely successful cases to diverge slightly in the course of years, whereas those in which there is a residual squint of about five degrees become parallel. The failures can be dealt with after a reasonable interval by re-operation. I think it a mistake to operate upon both eyes at one sitting. I would rather treat a squint by advancement and recession on one eye than by advancement of both external recti.

Concomitant Divergent Strabismus.

This is not nearly so common in children as the converging variety. When present in young children it is generally of the variety known as neuropathic. It is congenital and associated with complete lack of fusion sense. The only treatment is operation when the divergence becomes unsightly. Older children may suffer from a divergence due to myopia which is cured by the use of appropriate glasses. A blind eye or one with very poor vision often diverges, taking the axis of the orbit, which is, in a sense, the natural position for an eye which is not guided by vision.

Surgeon, Birmingham Eye Hospital, &c.

Special Articles.

THE PRESENT PROBLEM OF FOOT-AND-MOUTH DISEASE IN ENGLAND.

By J. A. Arkwright, M.D. Camb., F.R.C.P. Lond.

(*From the Lister Institute, Chelsea.*)

That the problem of foot-and-mouth disease is not one that is likely to be easily or quickly solved is evident from the large amount of careful experimental work which has been already done on the subject during the last 25 years. In 1898 Loeffler and Frosch began their long series of observations which have been carried on by them and their successors almost continuously since, on the nature of the virus and methods of producing immunity artificially in domestic animals. A great many valuable observations and experiments have also been made in France by Nocard, Vallée, Carré, and others, as well as in Italy, Holland, and elsewhere. The result of all this work has been that a platform of sure knowledge has been reached, but it cannot be denied that much information is still needed to complete the knowledge of the natural history of the disease, the nature of the virus, and still more to enable proper methods of repulse and attack in the face of epidemics to be devised.

Whilst briefly recapitulating the basal facts which have been ascertained it may be useful to indicate at the same time the chief gaps in present knowledge. The virus can be obtained free from recognisable bacteria or other microbes in a clear watery filtrate after passing it through a porcelain filter, and the original blister fluid may be so potent that when diluted 100,000 times one cubic centimetre is sufficient to infect a susceptible animal. The blood also is infective early in the disease. The virus as examined in the laboratory is rendered inert by a temperature of 60° C. (for five to ten minutes), but weak disinfectants—e.g., 1 per cent. carbolic—do not necessarily destroy it. Uncontaminated virus will keep and remain active in the ice-box for months. The disease can be communicated by scarification, subcutaneous or intravenous injection, or by feeding. Exposure to light or drying has usually rendered innocuous material which has been deliberately contaminated.

Against this positive knowledge must be set the extreme variability in activity of the virus, the tendency for it to die out during experimental passage and, on the other hand, the high degree of infectivity of the spontaneous disease and the readiness with which inanimate objects and contaminated ground appear to be implicated in the natural transmission of the disease. There are no accepted experimental data showing how long and under what conditions straw, litter and fodder, or byres and stalls can retain infection.

No microscopically recognisable organism has at present any plausible claim to acceptance as the cause.

Infectivity of Cases of Disease.—Susceptibility of Different Animals.

As regards the infectivity of living animals suffering from "foot-and-mouth" it is known that, as a rule, the disease can be easily transmitted by wiping the mouth or lips of a susceptible animal with material from a case of disease. It has also been shown by Loeffler that an animal is occasionally capable of passing on the disease to its neighbours in a cowshed after apparent recovery for as long as seven months from the onset of illness. It is believed that the virus may be imprisoned in the horn of the hoof and subsequently be set free in an active condition four months after the attack by the wearing away of the hoof. On the other hand, Vallée has shown reason to think that the period of infectivity during the acute stage is rather brief, but that it begins during the incubation period.

Concerning the susceptibility and liability to carry infection of man and animals in the farmyard, other than cattle, sheep, and pigs, very little has been definitely settled, though Hecker claimed that nearly all such animals, including cats, dogs, rabbits, and owls, could be infected and the disease transmitted from them to ungulates. Loeffler, without recording many experiments, admitted the possibility of all animals and birds, especially starlings, carrying the infection passively, but he failed to infect rodents and birds, &c.

Immunity.

A great deal has been learnt about the production of active and passive immunity. Though protective serum from horses, oxen, or pigs can be obtained, it is either inapplicable for other reasons or too expensive for general use. Active immunisation by direct infection, "*aphtisation*," is uncertain in its results on account of the difficulty of regulating the severity of the attack or foretelling the duration of protection. Temporary passive immunisation by the injection of the serum of recovered animals may be of great use in the presence of an extending epidemic, especially in connexion with active immunity produced by inoculation immediately with virus from a previous case. The blood of animals taken during an attack has been advocated by French workers as a means of producing an immunising general illness of short duration without local lesions. The great bar to the utility of these various methods is the short duration of immunity even after an attack of disease, when a second attack may occur in so short a time as six months or even sooner. It has also been found by Vallée that one strain of the disease does not always protect against another strain of virus even for a few weeks. Prophylaxis, raising the natural immunity by inoculation of foreign protein, has been advocated as an expedient with a view to modifying the severity of an attack.

Animals Suitable for Laboratory Research.

Closely connected with the question of the susceptibility of rodents, &c., is the choice of animals for research. Loeffler and his colleagues gave no support to the view that rabbits and guinea-pigs could be used as laboratory animals, but in 1921 Waldmann and Pape found that guinea-pigs could be infected with considerable regularity if the inoculation were made on the hairless skin of the metatarsus and that by this means vesicles could be produced there and in the mouth. This discovery was confirmed by Hobmaier, Uhlenhuth, and others, and great hopes were raised that by the easier and cheaper methods of research thus opened up knowledge would be advanced more quickly. The new technique does not, however, appear to have given much advantage so far, though the virus can be kept active by passage through a series of guinea-pigs and remain still infective for large animals. The amount of virus obtainable in this way is not enough for the hyper-immunisation of large animals, and no definite attenuation has been associated with passage in these rodents at all comparable to that in the case of small-pox and vaccinia. Nevertheless, the fact that rodents are susceptible, despite previous failures to infect them, is an important piece of knowledge.

Work in Great Britain.

Turning to work which has been done in this country, the opportunities have been very limited. In the first place "foot-and-mouth" has been a rare disease here in comparison with the state of things prevailing on the continent of Europe, owing to the adoption of the policy of slaughter which has had considerable success, though less effective recently. The result of this draconic measure has been to make serious clinical observation in the field of the disease, its progress, infectivity, and means of spread very limited and experimental study impossible.

When in 1921 the Ministry of Agriculture decided to inaugurate research on foot-and-mouth disease, it was with the especial hope that it would be possible to cultivate the virus and work out a method of immunising animals prophylactically. It was considered necessary that the work should be done entirely on board ship and a disused mine-sweeper and a lighter for animals were fitted up for the purpose. It was not till after the research was over that the method of working with guinea-pigs was published, but in any case experiments with calves, sheep, or pigs were then, as now, an essential to the work. It was necessary not only to maintain a stock of virus, but to make experimental inoculations with very limited accommodation.

Experience soon showed that operations could proceed only very slowly and must be seriously limited in their scope and often brought to a standstill by want of demonstrably active virus. The laboratory was open for work for seven months, from the end of November, 1920, to July, 1921, but for most of that time an active virus was not available. It was found necessary about the latter date to close down the research as the result of the urgent demands for general economy in Government departments together with the impossibility of holding out the prospect of much gain to knowledge in the immediate future under the existing circumstances. This aspect of the venture has been explained by Prof. Robert Muir in a letter to the *Times* of Jan. 14th, who at the same time points out that future research is needed, but must be carried out on land, of course, with careful arrangements for isolation.

As a brief summary of the kind of research which is urgently needed the following lines of investigation may be suggested.

1. Further study of the purified as well as of the natural virus, especially with regard to its resistance to drying and daylight, and its culture.

2. Search for some reliable laboratory method of diagnosis, especially for the recognition of slight cases of disease, whether by inoculation of small animals or by some immunological test.

3. The investigation of the natural means of spread with regard to (*a*) the period of illness which animals are most infective and how long infectivity remains; (*b*) the persistence of the contagion on inanimate objects; (*c*) whether other animals than ungulates—e.g., rodents and birds—become infected naturally or act as passive porters of the virus, and in either case whether they are efficient as agents for the transmission of infection to farm stock.

The Practical Issue.

It is to be hoped that Great Britain will soon again be free from infection and then it will be seen whether the country, the Ministry, and the farmers will have the faith and courage to set up and maintain a proper experimental station on land in a place which can be sufficiently isolated. An easier, if less enterprising and more ignoble path would be to leave the investigation to our enthusiastic French, Dutch, and German fellow-sufferers.

There is a further consideration which should stimulate this country to take seriously the need for investigation of the whole subject here. The problem in this country is not quite the same as abroad. There, where the disease is always present with constantly recurring epidemics, the main flow of energy and hopeful enterprise has been towards devising schemes for prophylaxis by vaccination or serum, and for treatment and cure. But here the main problems are, have been, and will again be, prevention of invasion and avoidance of spread. For these objects an efficient vaccine or serum or both would be an invaluable addition to the armamentarium and might cut short an epidemic when it had started. There may, however, be other means to the desired end more suited to the protection of our insular position. To this end careful study should be devoted to all obscure points in the natural history of the disease, and an investigation into the question of the occurrence of the disease in every likely or possibly implicated animal should be thoroughly undertaken, in addition to inquiries into other possible means of transmission.

MEDICINE AND THE LAW.

A Coroner on Anæsthetics.

Dr. R. L. Guthrie, coroner for East London, recently held an inquest upon the body of a girl 3 years of age, who died while under an anæsthetic after undergoing an operation for ear trouble. The medical evidence was to the effect that death was due to the shock of the operation while under the anæsthetic, and the coroner recorded a verdict of death from misadventure, expressing himself as satisfied that the operation was urgent and properly performed and that the anæsthetic (ether) was properly administered. Nevertheless he is reported to have added observations to the effect that the number of deaths occurring under anæsthetics is "disquieting" or "alarming," and that it is unfortunate that "nothing seems to be gained or learned from them from a medical and surgical standpoint." He added that he believed that "in America the subject has been gone into more fully and that the medical and surgical societies are doing far more than we appear to be doing in this country in that matter." In consequence of the coroner's words the inquest was very widely reported in the lay press, and it is to be regretted that such observations should be made without careful consideration and the fullest possible information, particularly in connexion with a death where the coroner himself was unable to attach blame to anybody, and to which they were consequently irrelevant. In America and in this country the elimination of risks due to the use of anæsthetics is a subject of anxious care to anæsthetists and surgeons alike, and to suggest an invidious comparison between the two countries is unjust and misleading. Meanwhile the public should be reminded that thousands of operations take place daily from which the highest skill of surgeon and anæsthetist cannot exclude the possibility of a fatal ending, but that it is only the fatal endings that come under newspaper notice. They must judge whether such endings are frequent or not, when compared with the number of occasions when anæsthetics are administered. They must also remember that "death under an anæsthetic" is a somewhat loose term. A death after an operation may take place before the patient has recovered from the anæsthetic, and yet its administration may have contributed little or nothing at all to the fatality. A death due to an anæsthetic would be one which would have taken place if there had been no operation, or in which death was definitely traceable in some substantial degree to its administration. Even then it might be a case of taking a known risk as the only possible means of saving a patient's life.

Cancer of the Scrotum in a Mule-spinner: a Test Case.

At the Stalybridge County Court, before Judge H. W. Bairstow, K.C., on Jan. 11th, an application was made under the Workmen's Diseases Act, 1906, which was in the nature of a test case, on behalf of an operative spinner—Harry Whiteley—against the owners of the mill in which the operative worked. The Operative Spinners' Association took up the case, and Mr. E. Wingate-Saul, K.C., appeared for the applicant. The point at issue is whether epithelioma of the scrotum, to which it appears mule-spinners have been particularly liable, is one contracted in the course of their employment, and for which they should be compensated. Mr. Wingate-Saul submitted that the disease which the applicant had contracted was epithelioma of the scrotum, and was caused by mineral oil in the course of his employment. The records of the Manchester Royal Infirmary showed that during the 20 years 1902–22 there were 141 patients treated for this disease, and 69, or nearly 50 per cent., of these cases occurred in mule-spinners; further, that in almost every case the spinners were affected on the left side of the scrotum. In order to find out why this was so, and why mule-spinners were so prone to this disease, medical men visited various cotton mills to study the conditions under which the men worked, and to see the mule-spinners at work. They found that on the machines which the men operated there was a carriage which moved backwards and forwards about three feet above the floor, and this had to be followed by the operators. In front of the carriage was a steel bar, which the medical men noticed was always splashed with the mineral oil used for lubrication of the spindles. Threads which were constantly breaking had to be pieced up by the operator, and as they did this the left side of the body constantly came into contact with the steel bar covered with oil. The temperature of the room in which the men worked was high, and the men wore no clothing beyond a pair of trousers and a shirt. Mr. Wingate-Saul submitted that it was the irritation set up by the mineral oil, combined with that caused by the constant friction against the metal bar, that was responsible for the disease. The disease usually manifested itself by the presence of a small wart which was frequently malignant from the beginning, and the only successful cure was an operation performed in good time. The applicant in the present case discovered about two years ago that he had a small scrotal growth, which gradually increased in size, and for which on August 4th last he underwent an operation. The only question before the court was that of liability. A sample of the oil used on the machine would be shown to be such a mineral oil as was described in the schedule of the Workmen's Compensation Act. Mr. Eastham, K.C., who appeared for the mill-owners, called for the production of the medical certificate upon which the application for arbitration had been based. According to the particulars the certificate was dated March 4th, 1923, and referred to the disease from which the applicant suffered as "epitheliomatous ulceration." The only certificate which Mr. Wingate-Saul could produce was one dated July 18th, which referred to the disease as "epithelioma of the scrotum." Application was made for leave to amend the particulars by an alteration of the date and name of the disease in accordance with the July certificate. It was submitted by Mr. Eastham that the judge had no jurisdiction, on the ground that the action would be based on a certificate which had no existence when the proceedings were started, and also that the right to appeal to the medical referee on the question of the validity of the certificate would be prejudiced. The judge expressed his regret that a case of serious importance to all engaged in the cotton industry should be held up on what he suggested were purely technical grounds. After a long legal argument the case was adjourned sine die in order to give Mr. Eastham an opportunity for appealing to the medical referee over the new certificate. As Mr. Eastham formally objected to the judge's ruling on the question of jurisdiction, it is possible that the case will next be raised in the Court of Appeal.

Illegal "Procuring of Drugs."

Yasukichi Miyágawa, a Japanese merchant, was convicted recently at the Central Criminal Court of "procuring" and doing an act preparatory to procuring 500 lb. of morphine hydrochloride for Miyágawa and Co., a firm at Kobe, Japan, and was sentenced under the Dangerous Drugs Acts of 1920 and 1923 to penal servitude for three years, to pay the costs of the prosecution, and to be eventually expelled from this country. His appeal against this sentence has now been dismissed by the Court of Criminal Appeal. The principal point raised was of some importance; being, briefly, that as the transaction, the subject of the prosecution, consisted in the purchase of the drug in Switzerland for shipment to Japan without any bringing of it to this country, it was not a case of procuring within the Statutes referred to and the regulations made thereunder. In the course of the argument for the appellant the Lord Chief Justice pointed out that the shipping documents for the carriage of the drugs from Marseilles to Japan were sent to England, and that shipping documents had been described as "the key of the warehouse." In

delivering the judgment of the court, Lord Hewart said that the Acts and the regulation chiefly in question (Regulation 3 made May 20th, 1921, under the Act of 1920), if compared, did not support the appellant's contention that the physical bringing of the goods to this country, or the intention to bring them, must be proved before a charge of procuring or attempting to procure could be sustained. The sentence was no doubt severe, but it was impossible to believe that the accused acted innocently.

The Case of Ball v. Howard.

An action against a medical man was heard before Mr. Justice Bailhache in the King's Bench Division of the High Court on Jan. 23rd and 24th, damages being claimed on the ground of negligence in the performance of an operation for appendicitis. It was stated that the plaintiff patient requested that a specialist should be called in, but the defendant said that this was not necessary. The plaintiff went on well at first, but complications arose, for which a consulting surgeon, who was called in, performed a second operation, followed by a good recovery. Mr. Bailhache, in giving judgment, found the practitioner's conduct in general to be worthy of the profession of which he was an honourable member, but that contrary to his usual practice and habit, he had committed two serious errors of judgment: (1) In not attending at once to the patient's call; and (2) by going away without leaving proper instructions what to do. The plaintiff having suffered no permanent harm, Mr. Bailhache gave judgment for him with £70 damages and the costs of the action, and judgment for the defendant on his counter-claim of 30 guineas fee with costs of the counter-claim.

The Kind of Person that Kills.

It is regrettable that the matter of legal responsibility enters so largely into the investigation of such terrible acts as the recent murder of two children by their nurse, to the exclusion of the scientific study of the kind of person that kills. Jealousy and anger are common human failings; murder is rare, but we are without detailed life-histories that might give us an understanding of the dispositions which underlie crimes of this nature, though even such histories would constitute only the approach to a subject which involves the fullest investigation of the mind of the criminal. The horror aroused by this deed should not shut out consideration of the mental stress and conflict that led to it, for the murderer's previous behaviour and undoubted love for her victims suggest an exaggeration and distortion of the noblest of instincts. The weapons of modern psychology have enabled us to understand something of the unconscious urgings of the minor delinquent; their application to such cases as this might add to knowledge whilst leaving to society the right to decide whether or how that knowledge should be applied.

TUBERCULOSIS.

Coördination of the Work of Tuberculosis Officers and Insurance Practitioners.

THE Ministry of Health has issued a Memorandum, dated December, 1923, on this subject (Memo. 286). It is a timely exhortation to coöperation, and it gives notice of certain alterations in the terms of service of insurance practitioners who, in the future, must send their initial and periodical reports on cases of tuberculosis direct to the tuberculosis officers instead of, as formerly, to the regional medical officer of the Ministry of Health. The Memorandum pays special attention to the cases in which tuberculosis is suspected but cannot be definitely diagnosed. These cases are almost incredibly numerous and, from the administrative point of view, are very difficult to deal with. Yet their successful handling would probably do more to stamp out tuberculosis than any other single measure. The Memorandum suggests that "it will usually be to the interest of the patient that the case should be referred to the tuberculosis officer, both in order that a second opinion may be obtained on the diagnosis, and in order that there may be no avoidable delay in giving the patient the benefit of any facilities available under the scheme of the local authority for diagnosis, treatment, or general care and supervision." This advice is, on the whole, sound, and it will be still more helpful when the tuberculosis service is staffed only by specialists in tuberculosis and not by medical officers of health who act as part-time tuberculosis officers and who have little or no special knowledge of tuberculosis. The Memorandum also lays down certain rules in order that there may be no doubt as to who is responsible for the treatment of a patient at any particular time. In the past the patient has been apt to fall between two stools, represented by the tuberculosis officer and the insurance practitioner respectively.

The Costs of Residential Tuberculosis Institutions.

A document, which promises to become an annual institution, has been published by the Ministry of Health under date December, 1923. It shows in tabulated form the cost of running the various public institutions for tuberculosis in this country. These tables are guaranteed to provide much disciplinary heart-burning and heart-searching, and they show at a glance that the administration of certain institutions is conducted on much more economical lines than that of others. Indeed, in some cases economy would seem to have been raised to such a high, or reduced to such a low, level (it all depends on the point of view) that it is natural to ask whether efficiency has gone hand in hand with economy. In one column the average number of the staff to each 10 beds is published, and it is noteworthy that at one institution this number is as high as 6·5, whereas in another institution it is as low as 2·3. As for the cost of living, the fluctuations are also great; at one institution the average cost per head for provisions is over 28*s.* per week, whereas at another institution this average is under 10*s.* It is pointed out that the information in these tables may be of substantial assistance in enabling the authorities concerned "to decide whether in a given case the various items of expenditure are on the lowest possible level compatible with efficiency." The publication of these tables should have a salutary effect not only on those institutions where expenditure is excessive, but also on those, if such there be, where expenditure has been reduced to a level incompatible with efficiency.

GYNÆCOLOGY AND OBSTETRICS IN SCANDINAVIA.

THE twenty-fifth anniversary of the Gynæcological and Obstetrical Society of Copenhagen has recently been celebrated by a special number of *Acta Gynæcologica Scandinavica*,[1] to which Danish and Swedish specialists in gynæcology and obstetrics have contributed 17 original articles. Some are of strictly limited interest; a paper on the occurrence of eosinophil cells in the appendix of the fœtus and new-born infant is not calculated to be of interest to many. But several of the papers are of both general and scientific interest, and they show, among other things, how closely Scandinavian gynæcologists are in touch with the outer world.

The Place of Cæsarean Section in Obstetrics.

There are two papers with this heading, and the authors represent opposite schools of thought. Prof. Elis Essen-Möller, of Lund, Sweden, discusses the risks of rupture of the scar of the classic Cæsarean section when the patient is again confined, and he holds that the importance of this risk has been exaggerated. If asepsis is maintained, and linen or silk sutures are used instead of catgut, there should be little chance of a weak scar being left. As for the choice between the classic and cervical sections, he finds that in

[1] Vol. ii., fasc. 3, 1923.

aseptic cases the two operations are about equally safe for the mother and infant; it is not yet possible to decide whether the scar in the uterus is more firm after one operation than the other. In defence of the classic operation he stresses its special advantages in cases of placenta prævia, in certain other emergencies rendering it absolutely necessary to remove the fœtus at once, and in the case of elderly primiparæ. But in cases suspected of sepsis he is not in favour of the classic operation, and of the two alternatives—the transperitoneal and the extraperitoneal cervical sections—he much prefers the former. Even when a case has been definitely septic, he notes that, according to the literature, better results, as far as the mothers were concerned, have been obtained with the transperitoneal than with the extraperitoneal operation. This has surprised him, for he had expected that germs would be more dangerous in the peritoneum than in the connective tissue, and that a phlegmon must be less serious than a peritonitis. At his hospital Cæsarean section has been performed in 132 cases since 1900, the chief indication being disproportion between head and pelvis (95 cases). Of the nine fœtal deaths, seven had occurred before the operation. Another fœtal death was due to congenital malformation of the fœtus, and the remaining fœtal death was due to defective ligature of the umbilical cord, the infant bleeding to death. Thus none of the fœtal deaths could be laid at the door of the operation itself. Among the maternal deaths there was one from peritonitis, one from intestinal obstruction caused by strangulation of a loop of the intestine between a myoma of the uterus and the pelvis, three were due to eclampsia, and one was probably due to air embolism.

The other paper on this subject is by Dr. Viggo Esmann, who seems to find certain objections to the growing popularity of Cæsarean section. In cases of habitual death of the fœtus a few weeks before term, he is in favour rather of inducing premature labour than of performing Cæsarean section. He takes the same line when difficult labour at term is anticipated on account of slight disproportion between the head and the pelvis. In 1916 he gave an account of 23 cases in which premature labour had been induced, and among these cases there were only four fœtal deaths, to two of which prolapse of the cord contributed. Since 1916 he has induced premature labour in 24 cases because he anticipated mechanical difficulties, and of the two infants who died, one was malformed and not viable. All the mothers left hospital in good health. Hence his conclusion that this procedure was more successful as well as more natural than the more radical undertaking of a Cæsarean section would have been.

Treatment of Dystocia Due to Bandl's Ring.

Dystocia due to Bandl's ring has recently been characterised as a figment of the imagination, but Prof. E. Hauch refuses to subscribe to this agnostic teaching and states that since the obstetrical service B of the Rigshospital in Copenhagen was started some dozen years ago, 25 cases of dystocia from this cause have been observed among about 20,000 confinements. In 12 of these cases the diagnosis of Bandl's ring was confirmed by abdominal palpation. This revealed a distinct furrow in the uterus which, in one case, was so marked as to give the uterus an hour-glass shape. In the rare cases in which this condition is diagnosed early, he is in favour of giving morphine and waiting for at least an hour in the hope that the contraction may pass off. He adds the warning that the morphine may render the infant oligopnœic at birth, artificial respiration being necessary for some time. In most cases, however, matters have proceeded so far that it is necessary to terminate labour as soon as possible, and the course to be followed must depend on whether the infant is already dead or not. In the former case, forceps may be applied or perforation and basiotripsy performed. Another procedure is decapitation with version and extraction. If, however, the infant is still alive, and the case is not already septic, the best procedure is transperitoneal cervical Cæsarean section. If this operation is contra-indicated, an attempt should be made to bring down an arm and apply forceps.

Kielland's Forceps.

The arguments for and against the use of Kielland's forceps are discussed by Dr. Oscar Horn, who has used them in 70 cases. He also summarises the bulky literature on the subject. He naturally finds that the authorities who have used these forceps extensively are greatly impressed by their superiority over other forceps, whereas the opponents of the Kielland forceps have either not used them at all or only seldom. Dr. Horn concludes that Kielland's forceps undoubtedly require a more accurate topographical diagnosis as well as more practice than the older and simpler forceps, but when these two conditions are fulfilled, Kielland's forceps may be most helpful in cases of difficult labour. He had only one maternal death (pulmonary embolism on the fourteenth day) among his 70 cases, and only six fœtal deaths. When he first began to use these forceps, he fairly often found a clear-cut mark close to the external canthus of one eye, but during the last few years he has not seen this mark. In three or four cases there was slight transitory facial paresis, but only in one case did it last as long as eight days.

Diagnosis of Pregnancy by the Induction of Glycosuria.

Dr. F. Jensen traces the development of these tests for pregnancy since 1920, when Frank pointed out that the administration of 100 g. of grape sugar by the mouth on an empty stomach provokes glycosuria in pregnant women but not in others. Subsequently two other tests have been devised, both of which also depend on the fact that the capacity for assimilating carbohydrates is reduced in pregnancy. One of these tests, associated with the names of Joseph and Kamnitzer, consists of injecting 2 mg. of phloridzin, which provokes glycosuria in the pregnant but not in others. The other test, that of Brinitzer and Roubitschek, consists of inducing glycosuria by an injection of adrenalin after 10 g. of grape sugar have been given by the mouth. Dr. Jensen has worked with Frank's test, which he has modified, and instead of giving 100 g. of grape sugar in every case, he gives 1 g. for every kilo of body-weight. He comes to the conclusion that though the blood-sugar examinations render this test tedious, and at present suitable only for hospital practice, it is remarkably trustworthy, giving useful information in cases of threatened abortion as to whether the fœtus is dead or alive. The phloridzin test may be easier, as it is not necessary to carry out blood-sugar examinations, but only when it is negative is its evidence of value.

The Ultimate Results of Menge's Hysterorrhaphia.

Dr. W. Ottesen, of the Diakonissestiftelsens Hospital in Copenhagen, has investigated the subsequent fate of the patients on whom Menge's hysterorrhaphia was performed in the period 1909–20. He succeeded in tracing 55, 40 of whom were re-examined in his own hospital, 10 were re-examined elsewhere, and 5 sent a written report of their health after the operation. Among the 50 who were medically re-examined, there were only two showing a definite relapse, and in neither of these cases was the uterus so much retroflexed that its fundus lay at the bottom of the pouch of Douglas. It was also found that subsequent pregnancies and labours had not been disturbed by this operation, the technique of which was described in 1904.[2]

Spurious Perforation of the Uterus.

Dr. H. Wulff records a remarkable case which may bring some consolatory reflections to obstetricians who have pleaded guilty to perforating the uterus while curetting it for an abortion. Dr. Wulff's patient was a married II-para, aged 39, who suffered from incomplete abortion in the eighth to the tenth week of pregnancy. Examination under ether anæsthesia showed the

[2] Centralblatt f. Gynäkologie, No. 21, 1904.

cervix to be soft, the external os admitting the tip of one finger. The body of the uterus was anteflexed, anteverted, freely movable, and very soft. Dilatation was started with Hegar's No. 12. Some difficulty was experienced with Nos. 16, 17, and 18. Dilatation proceeded somewhat more easily with the larger numbers, and was continued up to No. 26. A curette was now introduced to a distance of 14 or 15 cm., and some placental tissue was removed. It was suddenly found that the curette could pass a distance of 23 cm. without encountering the slightest resistance in various directions. On bimanual examination the uterus was so soft as to be hardly palpable. Perforation of the posterior wall of the uterus was diagnosed, and hysterotomia anterior vaginalis was undertaken. It was found that the cervix had not been injured, and when a finger was introduced into the uterus, its relaxed walls could be felt definitely contracting. The fœtus and some placental tissue were removed, and the interior of the uterus was carefully explored by palpation. At no point could any perforation be found. Though the patient's recovery was delayed by protracted fever, a malodorous vaginal discharge, and pneumonia, there were no signs of peritonitis, and she was ultimately discharged as cured, with satisfactory involution of the uterus and mobility of its appendages. Dr. Wulff assumes that this was a case of relaxation of the uterus and not of perforation, but he admits that, not having removed the uterus for examination, he cannot swear to its freedom from a perforation.

This special number of *Acta Gynæcologica Scandinavica* also contains an account, by Dr. J. Fog, of a case of considerable medico-legal interest. It was that of a female infant, found alive on a railway line, 10 minutes after an express train had passed. Though both parietal bones were fractured, death did not occur till six hours after the infant was found. The mother had evidently been overtaken by precipitate labour while in the lavatory of the train. This and many other papers make the anniversary number of this journal interesting reading.

SWITZERLAND AND THE OPIUM CONVENTION.

(FROM OUR OWN CORRESPONDENT.)

AT the last assembly of the League of Nations Switzerland was severely criticised by Dame Edith Littelton, the British delegate, for not having yet joined the Opium Convention. As a matter of fact, the Convention was signed in 1913 by the Swiss Minister at The Hague, but it was never ratified by the Federal Parliament. The reasons for this failure are several. One is constitutional. Legislation on general hygienic matters belongs to the cantons. The Federal Government cannot on its own power regulate the production and traffic of certain drugs. This belongs to the sphere of the different cantons. This constitutional difficulty was the cause that the question was allowed to sleep. As the drug-habit is practically unknown in Switzerland public opinion did not take much interest in the Opium Convention. On the other side there was the opposition of certain chemical industries which feared a considerable damage through the regulations of the Convention. Naturally in a small country like Switzerland the control would be much more effective than in a country with vast colonial possessions. It was feared that while inflicting an enormous damage on one of our flourishing industries the ultimate scope of the Convention would be frustrated by the Great Powers tolerating drug-production on a large scale in their colonies. This lack of confidence found recent expression by Dr. A. Jaquet, professor of pharmacology at the University of Basle. Prof. Jaquet writes:—

"Whoever studies the question since the opium wars cannot deny that this is a great enterprise of international hypocrisy; the States interested in opium production and opium traffic are hiding their fiscal interests under a humanitarian cover. The Opium Conference of Shanghai and the Conference at The Hague of 1911 were summoned with the definite object to suppress with all means the production of and traffic with opium. With time this object vanished in the background as the States interested in the opium commerce formulated so many conditions for their coöperation that the war against the opium pest become more or less illusory. Instead, the Conference concentrated its efforts more and more on the regulation of production and traffic of the alkaloids of opium and of cocaine with the object of curtailing both. . . . I am of opinion that it would be best if each country would deal separately in combating the misuse of morphia and cocaine without taking refuge in an International Convention of which the great would take but small notice and which would crush the small."

I have quoted these words of an impartial observer. His views are shared by many Swiss not in the least interested in the chemical trade. In the last years, however, opinion is coming round in favour of a speedy ratification of the Convention. This change is probably due to the influence of the League of Nations on the Opium Commission. The Federal Council has lately been strongly attacked both in the press and in Parliament for moving so slowly in this matter. Under this pressure the Federal Council has prepared a Bill on narcotic drugs which will shortly be submitted to Parliament. When this Bill has become law the Convention can be signed. Waiving some constitutional scruples the Government bases the Bill on a paragraph in the constitution empowering the Federal Council to take legislative action for combating epidemic diseases. The Bill, which is dated Dec. 12th, 1923, provides for the supervision of import, export, production, manufacture, storage, purchase, sale, and distribution of the following drugs: opium in all its forms, morphia and its salts and all preparations containing more than 0·2 per cent. of morphia; heroin, its salts and preparations containing more than 0·1 per cent. of heroin; coca-leaves; cocaine, its salts and preparations containing more than 0·1 per cent. of cocaine. Production of and trade in these drugs are only allowed with a Government licence. Export to other countries which have signed the Convention is only granted if the addressee has a licence for his respective country. This Bill may be taken as a clear indication that the Swiss Government intends to carry out loyally and scrupulously the provisions of the Opium Convention.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

Delhi: National Baby Week.

IMMENSE activity is being shown throughout India in connexion with a National Baby Week which is being held in all parts of the country during the third week in January. The "Week" is celebrated at Delhi so as to coincide with the meeting of the Legislative Assembly, and an effort is being made to direct the attention of India's new legislators to the appalling loss of human life which is going on throughout the Peninsula. As is well known, on an average 400 babies out of every 1000 born alive die before they complete their first year in the great Indian cities, and the rate is often much higher.

With a view to preventing the outbreak of plague in Delhi, the Public Health Commissioner with the Government of India has worked out a scheme for intensive rat destruction and the closing down of existing grain stores and their replacement by rat-proof buildings, but although the municipality is willing to provide half the cost of the proposed measures their execution is held up for want of help from the Government.

The recently founded University of Delhi, at which the Inchcape axe is levelled, issued its first report at Christmas. The report forms an excellent apologia for the University's existence, but there is already a flourishing university at Lahore, less than 300 miles away.

Lahore: A Professional Tax on Doctors.

The Lahore Municipal Committee recently proposed the imposition of a professional tax on medical men. As a protest against this measure a largely attended meeting of medical men was held in the city on Dec. 23rd, out of which a committee was appointed to initiate propaganda against the tax and to secure its withdrawal by the Lahore Municipality. It was pointed out that the only two callings which are affected by the proposed tax are the legal and the medical professions, and that if the scheme is carried out medical fees will have to be raised and the public may resort to the large number of quacks practising in the city whom the tax will not affect.

Calcutta: The Exhibition.

At the Calcutta Exhibition, open until the end of January, an exhibit of great interest is a chart by Dr. C. A. Bentley among the official exhibits of the Bengal Public Health Department. "The graph of prices and mortality of each district," he writes, "shows that the seasonal course of prices (of rice) is in all probability the main factor determining the peculiar seasonal mortality curve observable in Bengal, which differs markedly from that of the other provinces." It is clear that in Bengal measures aimed at restricting the prices of agricultural production may be fraught with the very gravest consequences to the health and welfare of the population whose prosperity is almost wholly dependent upon two factors—the general character of the harvest and the monetary return obtained from the sale of crops. If rice fetches a good price the mortality is low and vice versa.

For the establishment of a Pasteur Institute in Calcutta representations are being made to the Governor of India by the Bengal Chamber of Commerce. The nearest anti-rabic institute to the second city of the Empire is at Shillong, and as over a thousand patients were sent there from Bengal last year, it is difficult to resist the claims of the premier Presidency to an institute of its own.

Delhi, Jan. 11th.

SECRET REMEDIES:

FORMULAS DISCLOSED BY THE MAKERS.

PATENT medicines sold in Italy must have their composition stated on the label, and although the formula given may not be always the right one, it is of interest to learn the composition of some well-advertised British and American specialties as "disclosed" by the makers themselves. Of 62 such formulas, 10 were found to be practically identical with those given in "Secret Remedies."[1] 14 others differed materially from the B.M.A. analyses. The remaining 37 patent medicines were not mentioned in these publications. Quantities are given in grammes or cubic centimetres unless otherwise stated.

Formulas not Found in "Secret Remedies."

Albert's Grasshopper Pills.—Aloë barb., 0·12; Colocynth., 0·04; Jalap res., 0·02; Pulv. zingiber, 0·006; Sapo dur., 0·03.

Albert's Grasshopper Ointment.—Ol. oliv., 30; Ol. palm., 180; Res. coloph., 270; Cera flav., 60.

Allen's Foot-Ease.—Acid. salicyl., 5; Acid. boric, 45; Magn. silic., 50.

Angier's Throat Tablets.—Pulv. cort. ulm. fulv., 1·0; Extr. glycyrrh., 0·02; Extr. tussilago farf., 0·03; Paraff. liq., 0·15.

Antexema Granules.—Calc. sulphid., 0·06.

Battle's Bromidia.—Chloral hydrate, 15 per cent.; Pot. brom., 15 per cent.; Extr. hyoscyam., 0·12 per cent.; Sacchar, 15 per cent.; Syr. aurant., 15 per cent.; Extr. glycyrrh., 5 per cent.; Aq. aurant. cort. ad 100 per cent.

Battle's Iodia.—Extr. liq. Stillingio sylvat., Helonia lut., Pimpinella saxifraga., Menispermium offic., part. equal. ad 125·0; Pot. iod., 7·5; Ferr. pyrophosph., 5·0.

Bell's Pa-pay-ans.—Papain, 0·06; Carb. veget., 0·06; Sod. bicarb., 0·06; Ol. menth. pip., 0·002; Ol. gaulther., 0·002.

Bristol's Pills.—Aloë soc., 0·06; Pulv. rhei., 0·05; Pulv scamm., 0·03; Sapo dur., 0·02; Syr. simpl., q.s.

Cascarets.—Extr. casc. sagr. ("rendered non-bitter") 0·12; Extr. glycyrrh., 0·25; Ol. anis., Ol. menth. pip., Pulv. acac., Sacch. alb., q.s.

Collis Browne's Chlorodyne.—Chloroform, 6·0; Molasses 25·0; Extr. glycyrrh., 12·0; Morph. hydrochlor., 0·50; Ol. menth. pip., 0·10; Tinct. cannab. ind., 3·0; Tinct. capsic., 1·50; Syr. simpl., 35·0; Alcohol, q.s. ad 100·0.

Cuticura Pills.—Aloin, 0·02; Jalapin, 0·02; Podophyllin 0·008; Capsicin, 0·001.

Darley's Toothache Plasters (Johnson and Johnson).—Pimento, Piper nigr., Caryophyll., 10 per cent. of each; Rubber solution, q.s.

Elliman's Embrocation.—Acid. acetic (30 per cent.), 180; Ol. terebinth., 300; Camphor., 20; Ovi vitell., 100; Aq. dest., 400.

Evans's Pastilles ("Special formula for Italy").—Ol. pini essent., 0·01; Menthol, 0·002; Pot. chlorat., 0·003; Sod. biborat., 0·03; Extr. glycyrrh., 0·17; Pulv. acac., Sacch. q.s.

Fellows's Syrup of Hypophosphites.—Mang. hypophosph., Pot. hypophosph., Sod. hypophosph., Ferr. hypophosph., of each 0·009; Calc. hypophosph., 0·0005; Quinine, 0·003; Strychnine, 0·0011.

Foster's Backache and Kidney Pills.—Pot. nitr., 0·024; Ginep (? juniper), 0·005; Uva ursi, 0·008; Tereb. venet., 0·024; Excip., q.s.

Foster's Digestive Pills.—Podophyllin, 0·011; Leptandrin, Extr. hyoscyam., Aloin, of each, 0·008; Rad. (?) jalap, 0·004. "With tonics and laxatives."

International Chemical Co.'s Bisuroids.—Each tablet contains phenolphthalein, 0·135.

Ecorces d'arémone.—Sapo moll., 75; Glycerin, 25; Pot. iod., 15; Sod. biborat., 1; Citral., 2; Aq. dest., 88.

Fosfiron.—Ferr. nucleophosph., 0·06; Calc. glycerophosph., 0·3; Cinchona alkaloids, 0·05; Caffein, 0·03.

Kassium Extract.—Extr. "cassium lign.," 0·02; Rad. gossyp. barb., 0·04; Calc. glycerophosph., 0·15; Ferr. glycerophosph., 0·03; Ol. anisi, 0·0006; Excip., q.s.

Lactopeptine Powder.—Lactose, 40 oz.; Pepsin, 8 oz.; Pancreatin, 6 oz.; Diatase, 4 dm.; Acid. lactic., Acid. hydrochlor., of each, 5 fl. oz.

Langdale's Cinnamon Tablets.—Ol. cinnamom., 0·25; Pulv. acac., Sacch. alb., q.s. Coloured with carmine.

Langdale's Essence of Cinnamom.—Ol. cinnamom., 30; Tinct. cinnamom., 30; Alcohol (90°), 54.

Marshall's Cigarettes.—Lobel. inflat., 20; Datur. stramon 55; Piper cubeb, 20; Pot. nitr., 5.

Naldire's Worm Powders.—Nuc. arec. pulv., 4·0; Jala pulv., 0·5; Rosmarin pulv., 0.5.

New Skin.—Pyroxylin, 5; Acetone, 50; Benzole, 20; Amyl acetate, 25.

Norton's Pills.—Aloë cap., 0·03; Extr. gentian, 0·12; Ol. camom., 0·02; Pulv. gentian., q.s.

Pazo Ointment.—Zinc oxide, 10; Camphor, 5; Carbolic acid, 1; Balsam of Peru, 4; Extr. hamamel., 6; Cera flav., 4; Adeps benz., 70.

Reudel's Bath Saltrates.—Magn. carb., 0·005; Calc. carb. 0·005; Pot. carb., 0·00125; Calc. sulphat., 0·0025; Sod. chlor., 0·0012; Lith. carb., 0·00005; Sod., biborat., 0·10; Sod. bicarb., 0·305; Sod. carb., 0·50; Hydrogen sulphid 0·025; "Baregine," 0·025; "Oxygenated Salts," 0·03; Radio-active substances, traces; essent. aromat., q.s.

Roche's Embrocation.—Ol. caryophyll., Ol. succini., Ol. limon. of each, 15; Ol. olivæ, 55.

St. Jacob's Oil.—Ol. terebinth., 60; Ether sulph., 25; Camphor, 10; Rad. anchus, 0·25.

Salrads. Concentrated (*Tokalon*).—"The active constituents of rhamnus purshianus, ginger and gentian," with Caffeine, 0·30; Lithia, 0·5; and Alcohol, 2·5 per cent.

Scott's Emulsion.—Ol. morrh., 44; Glycerin, 16; Sodii calcii hypophosph. (1·25 per cent.), 20; Sol. sod. hypophosp. (0·625 per cent.), 20; Alcohol, tragacanth, Ess. oils, q.s.

Smedley's Paste.—Pulv. capsic., 4; Adeps pur., 60; Rad. anchus., 1.

Winter's Nature and Health Restorer.—Pulv. rhei, 0·06; Podophyllin, 0·001; Aloë, 0·06; Capsicum., 0·0005; Ment. puleg., 0·02; Extr. senn., 0·06; Menth. sativ., 0·02; Pulv. glycyrrh., 0·005.

Formulas Differing from "Secret Remedies."

In the following list the ingredients are given, first as stated on the Italian label, secondly (in parentheses) as stated in "Secret Remedies." Present but quantity not determined is denoted by n.d. A dash implies that the ingredient is not mentioned in one case or the other. As before, quantities are given in grammes or cubic centimetres unless otherwise stated.

Antipon.—Alcohol, — (0·4 per cent.); Acid citr., — (grs. 39·3); Syr. simpl., 10 (—); Coccus cact., 1 (n.d.); Aq. dest., 100 (ad 1 oz.).

[1] British Medical Association, 1909 and 1912.

Bishop's Varalettes.—Lith. citr., 0·12 (n.d.); Piperazin. 0·01 (n.d.); Sod. bicarb., 0·20 (n.d.); Acid. tart., 0·15 (n.d.). *Carter's Little Liver Pills.* Aloin, 0·020 (n.d.); Jalapin, 0·020 (—); Podophyllin, 0·008 (n.d.); Capsicin, 0·001 (—); Pulv. glycyrrh., — (n.d.).

Cadum.—Zinc. oxid., 20 (11·3); Sulph. (flowers), 5 (8·0); Methyl salicyl., 1 (—); Ol. cadini, 1 (7); Acid. boric, — (3·1); Acid. salicyl., — (0·8); Vaseline, 73 (60); Hard paraffin, — (10).

Doan's Backache and Kidney Pills. Pot. nitr., 0·024 (v); Ol. junip., 0·050 (m. 1); Extr. uvæ ursi, 0·050 (—); Pulv. fœnugreek,—(grs. 17); excipient, q.s. (grs. 6); f. pil. 1 (f. pil. xx).

Eade's Gout and Rheumatic Pills. Aloë barb., 0·03 (10 per cent.); Extr. colch., 0·016 (18 per cent.); Pulv. colch., 0·065 (35 per cent.); Excipient, q.s. (37 per cent.).

Guy's Tonic.—Acid. hydrochlor. dil., 0·60 (0·59); Acid. phosph. dil., 0·55 (0·52); Alcohol (95 per cent.), 2·50 (2.27); Inf. gent. co., 10 (40); Tinc. cocci, 0·25 (q.s.); Chloroform, 0·20 (—); Aq. chlorof., — (50); Aq. ad (100), 100.

Holloway's Pills.—Aloes, 0·03 (n.d.); Pulv. zingiber, 0·03 (n.d.); Sapo dur., 0·15 (n.d.); Excipient, q.s. (—).

Kay's Linseed Compound.—Morph. hydrochlor., 0·02 (0·021 per cent.); Chloroform, 1·08 (1·07 per cent.); Alcohol, 1·30 (1·3 per cent.); Extr. ipecac. liq., 0·70 (0·007 per cent. alkaloid); Syr. scillæ, 10·0 (n.d.); Extr. glycyrrh. liq., 10·0 (—); Malt, 20·0 (n.d.); Decoct. sem. lini., 20·0 (n.d.); Ol. anisi, — (n.d.); Syr. tolut., — (n.d.); Syr. simpl., ad 100 (n.d.).

Owbridge's Lung Tonic.—Syr. marubii, 25 (—); Sy. sem. lini. (?), 25 (—); Acet. ipecac., 7·50 (0·002 per cent. alkaloids); Malt, 25 (n.d.); Chloroform, 0·50 (0·3 per cent); Ol. anisi, 0·10 (n.d.); Ol. caryophyll., 0·10 (—); Ol. menth. pip., 0·10 (n.d.); Alcohol, — (2 per cent.); Capsicum, — (n.d.); Aq., ad 100 (—).

Peps.—Extr. glycyrrh., 25 (25); Sacch. alb., 70 (70); Ol. menth. pip., 0·50 (trace); Ol. anisi, 0·50 (trace); Ol. pini, 1·00 (—); Extr. capsic. liq., 0·20 (—); Acid. tart., 1·00 (—); Extr. tussilago liq., 1·80 (—); Resinous matter, — (0·7); Talc, — (4).

Whelpton's Vegetable (Purifying) Pills. (Whelpton's vegetable pills in Italy).—Aloë soc., 0·06 (n.d.); Pulv. rhei., 0·05 (—); Pulv. scammon., 0·03 (—); Sapo dur., 0·02 (—); Syr. simpl., q.s. (—); Colocynth, — (n.d.); Zingiber, — (n.d.); Gentian., — (n.d.).

Williams's Pink Pills.—Pot. carb., 0·07 (0·66); Ferr. sulph., 0·08 (0·75); Mang. oxid. pur., 0·02 (—); Sacch., 0·03 (0·2); Extr. gentian., 0·025 (—); Aloes, 0·009 (—); Magnesia, — (0·09); Pulv. glycyrrh., — (1·4).

Woodward's Gripe Water.—Sod. bicarb., 1·0 (1·08 per cent.); Sod. brom., 1·0 (—); Ol. anethi, 0·01 (—); Ol. carui, 0·02 (—); Sacch. alb., 20 (20·5 per cent.); Essent. oil, — (0·03 per cent.); Alcohol,—(3·8 per cent.); Aq., ad 100 (—).

The Services.

ROYAL ARMY MEDICAL CORPS.

Capt. M. St. C. Hamilton is placed on the half pay list on account of ill-health.

Lt. A. M. Simson to be Capt and to remain seed.

Temp. Capt. J. A. Marsden relinquishes his commn. and retains the rank of Capt.

RESERVE OF OFFICERS.

Lt.-Col. A. E. Master, having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

MILITIA.

Capt. S. Miller to be Maj.

TERRITORIAL FORCE.

Maj. W. Macdonald resigns his commn. and is granted the rank of Lt.-Col.

J. D. M. Cardell to be Lt.

Maj. T. H. Oliver (late R.A.M.C.) to be Maj.

INDIAN MEDICAL SERVICE.

Maj. J. N. Whitamore has vacated the appointment of superintendent of Ambala District Jail. Capt. L. S. C. Roche, M.C., has been appointed Cantonment Magistrate, Amritsar.

DEATHS IN THE SERVICES.

Brig. Surg. Maj. William Creagh, third son of the late Lt. James Creagh, who died on Jan. 18th in his eighty-sixth year, qualified with the diploma of the Royal College of Surgeons in Ireland in 1857. He obtained the L.S.A. two years later, when he also received his first commission in the Army Medical Service. Later he became attached to the Royal Horse Artillery and saw service in the Afghan War of 1878–80, when he was mentioned in despatches and received the medal. He retired in 1882.

Correspondence.

"Audi alteram partem."

YEAST AND CONSTIPATION.

To the Editor of THE LANCET.

SIR,—In an annotation with this title in THE LANCET of Jan. 26th reference is made to the recent work of Dr. L. Gross and it is stated that he "failed to confirm" the mucosal atrophy of the intestine in vitamin A deficiency described by me. The statements made in your editorial columns are, as a rule, so reliable that I feel compelled to point out that Dr. Gross himself does not draw such a conclusion in his paper. Nor can such a conclusion be drawn from his observations. He worked with adult rats of about 200 g. weight and subjected them to a vitamin deficiency for an average of only six weeks. It is well known to everybody engaged in this kind of work that adult rats are much less susceptible to vitamin A deficiency, than young rats. Thus with our homogeneous stock a young rat of 50 g. weight will develop keratomalacia after seven to eight weeks of vitamin A deficiency, while older rats of the same stock weighing 160–180 g. will only develop keratomalacia after five to six months or more. The atrophic change in the intestinal mucosa which I have described occurs in young rats after seven to eight weeks of vitamin A deficiency when they also develop the eye infection which has recently been shown to be associated with a similar atrophic change in one of the paraocular glands. It is therefore not to be expected that the experimental conditions of Dr. Gross's experiment could have shown the atrophic changes which we have observed. Dr. Gross has realised this clearly, for referring to my observations he writes: "I can only assume that the discrepancy in our results is due either to the fact that the rats which he employed were young and growing whereas mine were adult, or to a difference in the length of time on the diet." If Dr. Gross's observations of the effects of a six weeks' deficiency in vitamin A on adult rats were to be taken as failure to confirm the occurrence of an atrophic change in the intestinal mucosa, they should also be taken as a failure to confirm the occurrence of keratomalacia, which is absurd.

I am, Sir, yours faithfully.

W. CRAMER.

Imperial Cancer Research Fund, 8–11, Queen-square, London, W.C., Jan. 26th, 1924.

COLD AND HÆMOPTYSIS IN PULMONARY TUBERCULOSIS.

To the Editor of THE LANCET.

SIR,—In sanatoria for patients suffering from pulmonary tuberculosis cases of hæmoptysis often occur without any predisposing cause. The most common predisposing causes of hæmoptysis are over-exertion, excitement, strain from carrying heavy weights or from excessive coughing, traumatism. These causes do not usually exist in sanatoria, but still hæmoptysis occurs frequently enough to demand some investigation. In a series of 100 cases of pulmonary tuberculosis who have had hæmoptysis during their stay in sanatoria, I have tabulated the times of onset of the hæmorrhage as follows:—

Number of cases which have had hæmoptysis commencing between the hours of 9 P.M. and 7 A.M. ..	57
Number of cases which have had hæmoptysis commencing between the hours of 9 P.M. and 7 A.M., and in which on investigation the hæmoptysis could be put down to some predisposing cause	4
Number of cases which have had hæmoptysis commencing between the hours of 7 A.M. and 9 P.M. ..	39

Patients were all in bed between the hours 9 P.M. and 7 A.M.

It will be noticed from these figures that 57 per cent. of these cases of hæmoptysis occurred without any apparent predisposing cause. These 100 cases

(68 male adults and 32 female adults) were all moderately early cases of pulmonary tuberculosis, the temperature of their sleeping quarters being for all practical purposes that of the open air, but there appears to be no satisfactory explanation why hæmoptysis seems more likely to happen during the period patients are in bed, a point on which Fishberg [1] comments.

I think that sufficient attention has not been drawn to the temperature of the air. Barcroft and Marshall [2] have found that as a result of exposure to cold the volume of blood passed per minute by the heart into the circulation is increased. The amount of this increase varies from person to person. I would suggest that, as a result of the increased volume of blood passing through the lungs, hæmoptysis is more likely to occur during the time of the day when the temperature is lowest. The small arteries and capillaries of the diseased portion of the lung would be more likely to rupture. Owing to the blood-vessels of the lungs not being supplied with vaso-motor nerves, an increase in the amount of blood passing through the lungs will be accompanied by an increase of blood pressure in the arteries. Anders [3] in his investigations has found that hæmoptysis is more common during the months of December, January, and February. My cases have been collected regardless of the season, but from my own observations I have noticed that hæmoptysis is more common among patients suffering from pulmonary tuberculosis during the winter months and during sudden changes of temperature.

In the treatment of hæmoptysis some years ago it was customary to apply ice-bags to the chest or over the affected lung, and to give the patient ice to suck. Through the absence of any good results this method of treatment has been abandoned almost altogether. It would appear from the above that it did more harm than good.

I am, Sir, yours faithfully,

WILFRID SMITH,
Jan. 27th, 1924. Assistant Tuberculosis Officer, Leicester.

GERMAN BATTLE OF THE CLUBS.

To the Editor of THE LANCET.

SIR,—It may interest you to learn that the struggle of German medical men against the Government decree of November, 1923, is not yet finally decided, although the essential part of this decree has been withdrawn. Many of the contracts with approved societies (Krankenkassen) do not terminate until the end of March, and it is not clear what will happen then. An Inquiry Commission now sitting in the Reichs-Arbeitsministerium represents panel doctors and approved societies, with three impartial persons, and has hopes of reaching an understanding. It is curious and unfortunate that the Vereinigte Sozialistische Partei (V.S.P.D.), unlike your Labour Party, is against the panel doctors, who have only the support of the communists, although employed persons generally are on the side of the doctors. Great indignation has been called forth by the fact that the medical men attached to the V.S.P.D. in Parliament have taken the part of the approved societies and are endeavouring to form a society of medical men in Berlin submissive to the will of the approved society executive.

Far-seeing people are convinced that unless some fundamental simplification of the German National Health Insurance is achieved, the system cannot be maintained. Insured persons at present pay 10 per cent. of their income in insurance, while the services rendered by approved societies and disablement insurance offices are far less than before the war. It has been calculated that in the larger towns there is one approved society official for every 500 to 700 insured persons, and to these must be added many officers of the *Versicherungsamt*, of the *Oberversicherungsamt*, the *Landesversicherung*, and the *Reichsversicherungsanstalt*. The enormous sums thus spent in administration are only to be explained by the historical development of the health insurance statutes. It is clear that health insurance can only be maintained by simplification upon the English model, for it is well understood here that the combination of insurance against disablement and disease is a great improvement on the German system.

I am, Sir, yours faithfully,

Berlin-Wilm., Jan. 25th, 1924. ROBERT GÜTERBOCK.

*** Dr. Güterbock's letter was written before he could have seen our summary of his article in the *Medizinische Klinik*. His letter may be regarded as a postscript to the comparative account of English and German Health Insurance given on p. 212 of our last issue.—ED. L.

BLOOD-COMPATIBILITY OF MOTHER AND INFANT.

To the Editor of THE LANCET.

SIR,—In the report of the proceedings of the Liverpool Medical Institute at its meeting on Dec. 20th last, appearing in THE LANCET of Jan. 5th, Dr. Norman Capon, discussing the question of transfusion in a paper on Hæmorrhagic Diseases of the New-born, is reported as having stated that "the mother is generally selected as donor and preliminary grouping is then not necessary." May I be permitted to point out that the implied assumption that the blood of mother and child are necessarily compatible is not justifiable; they may be, and frequently are, of different and incompatible groups. The fact that isoagglutinins do not usually appear in the infant's serum until some months after birth may render it possible to use any blood for transfusion, regardless of its group, without disastrous results in a young child, though, as there is no certainty when isoagglutinins may appear, this procedure cannot be regarded as entirely safe.

I draw attention to this matter because although, for the reasons put forth above, transfusion of an infant with the mother's blood, when incompatible, may be unattended by serious result, this would certainly not be so in the case of an older child.

I am, Sir, yours faithfully,

S. C. DYKE.
St. Thomas's Hospital, London, Jan. 22nd, 1924.

TUBERCULOSIS WORK IN ENGLAND.

To the Editor of THE LANCET.

SIR,—I am sorry to offer any criticism on Dr Salusbury MacNalty's able article on this subject in last week's issue of THE LANCET, but there is one paragraph I should like to comment on.

Talking of medical progress under the subheading of Artificial Pneumothorax, he says: "... this method of treatment may arrest the disease, or at all events prolong life, and should be practised more frequently than at present. I cannot speak with such eulogy of thoracoplasty, though favourable results are reported in a minority of cases."
